Capt (acting Major) WILLIAM HAIG FERGUSON.—For conspicuous gallantry and devotion to duty. When the advanced dressing station was completely destroyed by shell fire and everyone was ordered to take cover, this officer left his dug-out and carried several wounded, unaided, some hundred yards to safety, passing through a zone of gas and heavily shelled area. He did the same thing again later on.

Capt. (acting Major) ROBERT ALEXANDER FLOOD.—For conspicuous gallantry and devotion to duty. With the enemy within 300 yards of a divisional rest station he got a car loaded with wounded and took those who could walk and one stretcher case across the fields. Although knocked down by a H.E. shell, he finally got them to shelter.

Temp. Capt. AUGUSTIN POWNALL FRY.—For conspicuous gallantry and devotion to duty in going from place to place across the open, under heavy machine-gun, rifle, and shell fire, to attend to the wounded. His absolute fearlessness undoubtedly saved many men from bleeding to death. Throughout he displayed devotion to duty of a high order.

Capt. WILLIAM CLARKE GIVENS, Canadian A.M.C.—For conspicuous gallantry and devotion to duty. He organised and maintained for two days under shell and rifle fire a first-aid post, rendering aid to a large number of cases. Next day he established a dressing station, where he worked for 60 hours without relief.

Capt. (acting Major) HENRY NORMAN GOODE.—For conspicuous gallantry and devotion to duty. He was in charge of the bearers collecting wounded, and frequently visited his posts under very heavy shell fire. He organised the evacuation of the casualties from the regimental aid-posts to the advanced dressing station, frequently being obliged to alter his routes and establish new relay posts, owing to the heavy shelling. It was largely owing to his courage and energetic ability that the removal of the wounded was carried out in such a speedy and efficient manner.

Capt. FRANCIS HENNESSEY GOSS.—For conspicuous gallantry and devotion to duty. This officer worked all night in the open in front of the line, under heavy fire, dressing the wounded and carrying them back to safety. His temporary aid-post was captured and his staff made prisoners, but he made his way back through the enemy lines alone. The following night he made many journeys into the open, carrying wounded on his back to temporary shelter. His devotion to duty saved many lives.

Temp. Capt. (acting Major) FRANK CYRIL GREIG.—For conspicuous gallantry and devotion to duty. He was in charge of the advanced dressing station for five days, working under very heavy fire the whole time organising the disposition of his bearers. When the post was almost completely destroyed by shell fire some of his men were buried in a dug-out, and he worked with unremitting energy under heavy shell fire to get them out.

Temp. Capt. CHARLES HOPE HADDOW.—For conspicuous gallantry and devotion to duty. When the enemy drove the line back to battalion headquarters he kept his aid-post established until they were within 200 yards, and succeeded in evacuating all wounded. Later, during a counter-attack, he showed untiring energy in dressing and evacuating wounded under very trying conditions. He showed fine devotion to duty.

Temp. Capt. ALFRED ERNEST HALLINAN.—For conspicuous gallantry and devotion to duty. When his aid-post was surrounded by the enemy, he got through to battalion headquarters, reported on the situation, and established an aid-post there, where he evacuated a large number of wounded. Later, he worked for hours at another aid-post, while the enemy were within a few hundred yards. He displayed great energy and efficiency.

Temp. Capt. CHESTER HARRIS.—For conspicuous gallantry and devotion to duty. When the enemy was attacking in large numbers he, in spite of the heavy shell and intense machine-gun fire, succeeded in clearing all the wounded, and three times went back through heavy barrage to dress and carry in wounded men. His conduct was admirable.

Capt. (acting Major) JOHN HENDERSON HUNTER.—For conspicuous gallantry and devotion to duty while in charge of advanced dressing stations, which were continually shelled.

Capt. GEORGE KINGSLEY EDWIN INMAN.—For conspicuous gallantry and devotion to duty. Hearing that the infantry were heavily engaged, he obtained permission to go forward and help them. He found that the position was being heavily shelled and that the regimental medical officer had been killed. He at once assumed medical charge of the battalion, and though the infantry had retired twice took stretcher-bearers back to the position, and thus rescued many wounded who might otherwise have been captured.

Temp. Capt. CHARLES GEORGE LAMBIE.—For conspicuous gallantry and devotion to duty in tending wounded under intense hostile barrage, constantly going out into the open and bringing wounded in. On a later occasion he went from battery to battery under heavy shell fire, dressing the wounded and getting them away to the nearest ambulance. He was several times hit by shell splinters.

Temp. Capt. JOHN GAGEN LEE.—For conspicuous gallantry and devotion to duty in attending to casualties under very heavy machine-gun and shell fire continuously for four days. He was wounded on the second day, but remained at duty. He had his dressing station blown up twice. Each time new stations were reorganised very quickly. He behaved splendidly, and his conduct was a very fine example to all.

Temp. Capt. (acting Major) FRANCIS CHARLES LEES.—For conspicuous gallantry and devotion to duty while in charge of the arrangements for the evacuation of wounded. For 48 hours he worked unceasingly in an advanced dressing station, and owing to his courage and energy a large number of wounded were cleared from the forward area under most difficult circumstances.

Temp. Capt. SIDNEY JOHN LIDDON LINDEMAN.—For conspicuous gallantry and devotion to duty. For ten days he worked unceasingly, tending wounded under heavy fire, saving many lives. On one occasion, under intense machine-gun fire, he still continued dressing and collecting wounded, and his complete disregard of danger set a fine example to those under him.

Temp. Capt. (acting Major) JOHN WYCLIFFE LINNELL.—For conspicuous gallantry and devotion to duty in dressing and evacuating wounded under shell fire, during five days' operations. On two of the days, at great personal risk, he cleared wounded from villages which were being shelled.

Temp. Capt. VERNON EDMUND LLOYD.—For conspicuous gallantry and devotion to duty. While in charge of stretcher-bearers he worked for hours under shell fire, evacuating wounded; and in an advanced dressing station exposed to shell fire he dressed and evacuated a large number of wounded.

Temp. Capt. GEORGE ALBERT LYONS.—For conspicuous gallantry and devotion to duty. During four days' heavy fighting he worked unceasingly. When the regimental aid-post was heavily shelled he organised a carrying party and removed all men incapable of walking. He was the cause of saving many lives.

Capt. JAMES McLEAN MACFARLANE.—For conspicuous gallantry and devotion to duty. This officer, while a town was being heavily bombarded, frequently entered it to attend to the wounded who required surgical aid before they could be evacuated. Later he attended to the wounded, and evacuated them to the casualty clearing station, for three days working day and night, and when compelled to leave owing to the heavy shelling took his party to man a bridge over a canal, carrying on until ordered to leave just before the bridge was blown up. He was responsible for the saving of many lives.

Temp. Capt. JAMES DAVID MACKINNON.—For conspicuous gallantry and devotion to duty. During very heavy fighting he attended to the wounded in the open under machine-gun and rifle fire. He showed fine courage and saved many lives.

Temp. Capt. KENNETH DUNCAN CAMERON MACRAE.—For conspicuous gallantry and devotion to duty. He constantly attended to wounded under machine-gun and shell fire. He also maintained an aid-post on the line of the enemy's artillery barrage. By his devotion to duty many lives were saved.

Capt. (acting Major) ALEXANDER CROSS MALLACE.—For conspicuous gallantry and devotion to duty when in charge of advanced dressing stations. He worked continuously under shell fire, and when our troops had to retire he remained to clear his last cases until the enemy was within 100 yards.

Capt. (acting Major) WILLIAM McCOMBIE.—For conspicuous gallantry and devotion to duty. He repeatedly visited, under very heavy fire of all descriptions, the aid-posts he was engaged in clearing, personally conducting his bearers with complete disregard for his own safety in those localities where the fire was most heavy. Under very trying circumstances he showed great devotion to duty.

Temp. Capt. (acting Major) FRANCIS DE SALES McMENAMIN.—For conspicuous gallantry and devotion to duty. He worked day and night, getting into touch with regimental aid-posts and evacuating their wounded under heavy shell and machine-gun fire. By his untiring devotion to duty he saved many lives.

Temp. Capt. DAVID GAIR McRAE.—For conspicuous gallantry and devotion to duty while in charge of an aid-post during an enemy attack. Hearing that a siege battery was being heavily shelled and had many casualties, he at once proceeded, with a non-commissioned officer, to attend to the wounded in the battery position, and stayed there, under shell fire, for an hour. Throughout he showed fine disregard of his own safety and great devotion to duty.

Temp. Capt. JOHN PEARSON McVEY.—For conspicuous gallantry and devotion to duty. He organised and established aid posts near the front line under heavy shell fire and dealt with a large number of casualties. Though short of dressing, stretchers, and bearers he successfully evacuated many wounded, while 10 out of 18 of his staff were casualties.

Capt. CHARLES GRAHAM MEADE.—For conspicuous gallantry and devotion to duty. While brigade headquarters were being shelled this officer worked unceasingly, attending wounded gunners and infantry. Later, on receiving an urgent message from a battery, he set off by himself through a heavy barrage, and though suffering from the effects of gas, performed his duties in the open, regardless of all danger. He behaved splendidly.

Capt. HARRY MIDDLETON.—For conspicuous gallantry and devotion to duty during an enemy attack. Though suffering from the effects of gas, he remained at duty dressing wounded for four days until ordered to hospital. He was frequently under shell fire and had to change his aid-post several times.

Temp. Capt. ALEXANDER DRYDEN MOFFATT.—For conspicuous gallantry and devotion to duty at an advanced dressing station. He worked continuously under shell fire for 18 hours, dressing a large number of wounded. The dressing station was hit three times, but he carried on his work in a cellar.

Temp. Capt. DUNCAN COLLINGWOOD OGILVIE.—For conspicuous gallantry and devotion to duty while in charge of a walking wounded collecting post. For 16 hours he worked single-handed under heavy shell fire, dressing and evacuating wounded. Later he reopened a dressing station which had been evacuated and worked there for 48 hours.

Temp. Lieut. JAMES CARTER OGILVIE.—For conspicuous gallantry and devotion to duty. As medical officer of the battalion he did excellent work during four days' strenuous fighting. He was continually up and down the firing line, personally attending to wounded men, and caused all men known to be wounded to be got away. He set a very fine example to his stretcher-bearers.

Capt. GEORGE PERKINS.—For conspicuous gallantry and devotion to duty. After being in the firing line all day, he went out after dark with stretcher-bearers, and stayed out most of the night tending wounded.

Temp. Capt. HOWARD GEORGE PESEL.—For conspicuous gallantry and devotion to duty in evacuating all the wounded under severe and almost continuous shell fire. His three successive collecting posts were destroyed by shell fire and he himself was wounded, but he remained at duty, declining to be relieved.

Capt. AUBREY RADFORD.—For conspicuous gallantry and devotion to duty. He established a dressing station, collected a large number of wounded cases, and by his own personal example and initiative arranged for the evacuation of those wounded, and so saved them falling into the hands of the enemy. The whole time his work was carried out under heavy shell fire.

Temp. Capt. (acting Major) ALEXANDER WILLIAM RATTRIE.—For conspicuous gallantry and devotion to duty. He dressed and evacuated wounded in an advanced dressing station under heavy shell fire for many hours. When the station became practically destroyed, he, though gassed, succeeded in evacuating all the wounded over open country to another dressing station, where he continued to work until that, too, became untenable. He showed great pluck and determination.

Temp. Capt. STANLEY ALFRED RIDDETT.—For conspicuous gallantry and devotion to duty. This officer was the only medical officer in a village that was being very heavily shelled by the enemy, and where our troops were suffering severe losses. He showed complete and self-sacrificing disregard of danger, dressing the wounded and arranging for their removal, moving about the village, which he would not leave until he had satisfied himself by personal investigation that all the wounded had been evacuated. His gallant behaviour and devotion to duty undoubtedly saved many lives.

Temp. Capt. (acting Major) JOHN RODGER.—For conspicuous gallantry and devotion to duty. The position of his advanced dressing station had to be moved on four separate occasions, and on each occasion he evacuated the wounded with great skill. It was largely due to the fine example set by him under heavy machine-gun and rifle fire that the wounded were all got away. He has shown a fine spirit and set a great example throughout.

Capt. (acting Major) JOHN ROWE.—For conspicuous gallantry and devotion to duty. Although it was known that the enemy had penetrated the line, and the area in rear of the advanced dressing station was being organised for defence, this officer never lost touch with the regimental aid-posts. He made many journeys throughout the day, at all times under heavy fire, personally superintending the evacuation of the wounded.

Temp. Capt. BASIL SAMPSON, South African M.C.—For conspicuous gallantry and devotion to duty. During a counter-attack on the enemy positions, this officer, with another, improvised an advanced dressing station and relay posts under the most difficult conditions. They remained at a point considerably forward, under very heavy shell and machine-gun fire, and it was largely due to their efforts and able dispositions that a great many wounded were dressed and evacuated who otherwise might have fallen into the hands of the enemy when later they forced back our line.

Temp. Capt. WILLIAM SMITH, South African M.C.—For conspicuous gallantry and devotion to duty. During a counter-attack on the enemy positions, this officer, with another, improvised an advanced dressing station and relay posts under the most difficult conditions. They remained at a point considerably forward, under very heavy shell and machine-gun fire, and it was largely due to their efforts and able dispositions that a great many wounded were dressed and evacuated who otherwise might have fallen into the hands of the enemy when later they forced back our line.

Temp. Capt. GEORGE WHELDALE STANLEY.—For conspicuous gallantry and devotion to duty in going to the assistance of four wounded men, dressing their wounds, and getting them removed to a place of safety under heavy shell fire. His disregard of danger not only probably saved their lives but was an inspiration to others.

Capt. JAMES STEEL.—For conspicuous gallantry and devotion to duty. This officer was one of the few regimental medical officers who were with their unit during the whole period of withdrawal. He was indefatigable in dressing the wounded, often under fire, and when he had to move invariably assisted himself in evacuating the worst cases. Although twice wounded himself, he refused to leave his work, except to have his wounds dressed.

Temp. Capt. GEORGE EDWARD STEPHENSON.—For conspicuous gallantry and devotion to duty. He organised the most advanced dressing station in the area, attending to casualties of all units under heavy fire, in the most adverse circumstances, and in the open. His devotion to duty was of the greatest value.

Temp. Capt. JOHN STEVENSON.—For conspicuous gallantry and devotion to duty in attending to wounded under heavy shell fire. Subsequently he went out into "No Man's Land" under heavy machine-gun fire and brought in a wounded officer. His coolness and devotion to duty saved many lives.

Temp. Capt. (acting Major) ROBERT SVENSSON.—For conspicuous gallantry and devotion to duty. Under heavy bombardment he led motor ambulance wagons to an advanced dressing station, and brought away all helpless cases. Later he led a convoy of ambulance wagons under shell and machine-gun fire to aid-posts, and continued going backwards and forwards until he had got all wounded away. He saved many wounded from being abandoned to the enemy, and did fine work.

Capt. WILLIAM TAYLOR.—For conspicuous gallantry and devotion to duty in his work amongst the batteries. He remained to the very last in each position, attending to the wounded officers and men, and was untiring in his efforts to assist in every way.

Capt. EWING GEORGE THOMSON, Australian A.M.C.—For conspicuous gallantry and devotion to duty. This officer tended wounded in the open from 4 A.M. to 11 A.M. one morning. During this period he was under very heavy high-explosive and gas bombardment, but, although suffering from the effects of gas, he stuck to his aid-post. His rapidity in evacuating wounded from the gassed area no doubt saved many lives.

Capt. JAMES ETTERSHANK GORDON THOMSON.—For conspicuous gallantry and devotion to duty. When his dressing station was blown up, although suffering from gas, he continued to dress the wounded, and successfully evacuated all the stretcher cases, working until he was quite exhausted. On another occasion when a regimental aid-post was blown up he carried on dressing the wounded and successfully evacuated them. His devotion to duty was an inspiration to all under him.

Capt. WILLIAM ERNEST TYNDALL.—For conspicuous gallantry and devotion to duty. For five days this officer dressed wounded under intense fire, and during the withdrawal he many times stayed behind without assistance to look after them, being in imminent danger of capture. His unceasing efforts resulted in the saving of many officers and men. Though by no means physically strong, he never relaxed his efforts, and his cheerful example greatly heartened the men.

Lieut. DOUGLAS JAMES VALENTINE.—For conspicuous gallantry and devotion to duty. He attended to the wounded in the open under heavy shell fire and superintended their evacuation under most difficult circumstances.

Capt. (acting Lieut.-Col.) GIFFORD TRAILL VAN DER VIJVER.—For conspicuous gallantry and devotion to duty under very heavy hostile shell fire. He continued to work at his dressing station until it was no longer tenable, and before evacuating, under orders, cleared all casualties in the vicinity and brought his unit away with all the equipment.

Temp. Capt. JOHN WALKER.—For conspicuous gallantry and devotion to duty in carrying on his work at an aid-post which was continually being shelled. His organisation and arrangements for the work were admirable, 120 wounded passing through his hands, all congestion was avoided, and the despatch with which they were collected and evacuated probably saved several lives.

Temp. Lieut. ROWLAND WARD.—For conspicuous gallantry and devotion to duty. Whilst under a very heavy barrage this officer attended to the evacuation of numerous casualties. The aid-post situated in a small quarry was subjected to prolonged bombardment and heavily gassed, it was crowded with stretcher cases, and there were 60 more lying in the quarry. He went round all the cases, adjusting gas masks. The aid-post was not even splinter-proof, and received one direct hit, but he continued for three days and nights attending to the cases without sleep, and eventually got away the last of the casualties.

Temp. Capt. EDWARD PARKER WELMAN WEDD.—For conspicuous gallantry and devotion to duty in traversing shell-swept roads and searching trenches under heavy fire till he found and tended the many wounded.

Capt. (acting Major) ERIC WATSON WILLIAMS.—For conspicuous gallantry and devotion to duty. He maintained advanced dressing stations under heavy shell fire until the last possible moment, and personally superintended the evacuation of the wounded. Through his energy and devotion to duty all cases were cleared without delay.

Capt. (acting Major) ARTHUR LOWNDES YATES.—For conspicuous gallantry and devotion to duty. He maintained his medical posts under heavy shelling as long as it was possible, and was responsible for the collection and evacuation of several hundred wounded of other divisions, as well as a great many of his own.

FOREIGN DECORATIONS.

Belgian.

Croix de Guerre.—Staff Surg. H. Cooper, D.S.O., R.N.

Hellenic.

Order of the Redeemer: Officer.—Staff Surg. J. C. Bringan, R.N.

Our attention has been called to an advertisement in THE LANCET of Saturday, Sept. 14th, in which Brevet Lieut.-Colonel F. W. Mott, R.A.M.C. (T.), is described as Officer in Command of the Maudsley Neurological Clearing Hospital. Lieut.-Colonel P. H. Falkner is the Officer in Command, Colonel Mott being Senior Consulting Neurologist, but the mistake on the part of the Oxford Medical Press appears to have Parliamentary support, as Lieut.-Colonel Mott was described in the House of Commons by Mr. Macpherson as Officer in Command.

OBITUARY OF THE WAR.

CHARLES DEVEREUX MARSHALL, F.R.C.S. ENG.,

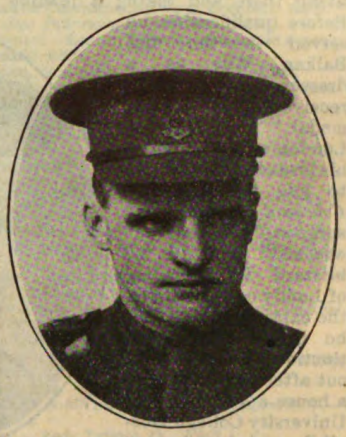
STAFF SURGEON, R.N.V.R.

Staff Surgeon Devereux Marshall, who died of cholera at Colaba War Hospital, Bombay, on Sept. 14th, whilst on active service, aged 50, was the son of the late William Marshall, solicitor, of Southsea, and received his medical education at University College Hospital, where he held the junior appointments after qualification. In 1902 he took the Fellowship of the Royal College of Surgeons of England and was appointed surgeon to the Royal London Ophthalmic Hospital, where he acquired a just reputation for great operative skill. He took a deep interest also in various questions on the scientific side of his special work and was particularly interested in colour vision. He wrote a very lucid book on diseases of the eye for the use of general practitioners and students, and contributed papers on ophthalmological subjects to several well-known compendiums. He joined the R.N.V.R. (London Division) in 1903, was promoted lieutenant 1906, transferred to medical branch 1909, promoted staff surgeon 1916. He served in a Flagship in the Mediterranean and in the Far East since 1914, and in 1917 was P.M.O. in the Persian Gulf. He was on active service during the whole of the war.

HEBER HAVELOCK MOSHIER, M.D. TOR.,

LIEUTENANT-COLONEL, C.A.M.C.; O.C. A CANADIAN FIELD AMBULANCE.

The son of Mr. D. D. Moshier of Toronto, the late Lieutenant-Colonel Moshier was born in Lambton, Ontario, in January, 1889. After graduating with distinction in medicine at the University of Toronto, at the age of 20, he undertook research in pathology at the Rockefeller Institute, New York, and later, crossing to England, worked with Professor Halliburton in the physiological laboratories at King's College, London. Returning to Canada, he had scarcely established himself at Calgary as a consultant pathologist when he was called to the University of Alberta, Edmonton, to the recently established chair of physiology. He threw himself into the work of the University with characteristic thoroughness and energy, and in three years showed himself a source of great strength to the faculty. While at first it seemed to him that his duty lay with the young university, as the war progressed he realised that his country had the greater call upon him, and when, early in 1916, the 11th Field Ambulance was raised in Alberta, he joined it. So good a name had he made for himself as a leader that, despite his youth, he was given his majority and placed second in command. That August he crossed to France with his unit, and went through the actions of Courcelette, Vimy Ridge, and Passchendaele. In September, 1917, he was given command of the unit, and later promoted Lieutenant-Colonel. In this position he rapidly gained the respect and affection of all under him. In May of this year he was mentioned in despatches. He met his death on August 29th during the recent operations, while proceeding forward to locate an advanced dressing station. Under 30 years of age, he had accomplished much, and with him Canada loses a man of great promise.



JOHN PROCTOR, M.B., CH.B. ABERD.,

MAJOR, ROYAL ARMY MEDICAL CORPS.

Major John Proctor, who died of wounds on August 12th, was the eldest son of the late William Proctor and Mrs. Proctor, of Ballater. In 1909 he graduated in Arts at the University of Aberdeen, and in 1913 took his medical degree with distinction, being immediately appointed to a resident post at the Royal Infirmary, Aberdeen, and becoming later house surgeon to the Aberdeen Hospital for Sick Children. He obtained a commission in the Royal Army Medical Corps on the outbreak of war and was sent to France, where he joined a cavalry field ambulance. He was promoted captain after a year of service, and in April, 1918, was mentioned in despatches and promoted to the rank of major. During the whole four years of service he was with the same division of cavalry. He was severely wounded on the night of August 11th, and died at the casualty clearing station the following morning. A brother officer has communicated to his relatives the following: "He was very brave and cheerful through it all, and everyone is full of admiration of his spirits. His loss to the ambulance is irreparable." Major Proctor was 30 years of age.

WILLIAM HOWARD LISTER, M.R.C.S., L.R.C.P. LOND., D.S.O., M.C.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain W. H. Lister was killed in Italy on August 9th, at the age of 32. He had gone forward in the discharge of his duty, and after being slightly wounded by a bullet was shortly afterwards killed by the concussion of a 15-inch mortar bomb. He was educated at Ackworth School, being a member of the Quaker Society, and entered as a medical student at University College, London, in 1904. While there he took a large share in the founding of University College Hall, Ealing, and maintained his interest in it till his death, living there and taking a leading part in its social life. Before qualification he served in the first Balkan War as a dresser, for which he received the Greek medal. Returning to London and qualifying, his love of travel led him to join the R.M.S.P. *Cobequid* as temporary surgeon, and he was wrecked in an ice blizzard in the Bay of Lundy on the voyage, the captian stating that he behaved with distinction. The war broke out after his election to a house appointment at University College Hospital, and he at once joined the R.A.M.C.,

taking part in the Mons Retreat and the first battle of Ypres. During the latter he was awarded the M.C. for an act of gallantry. His right elbow was injured and permanently ankylosed, but in spite of this, and after serving in the Mediterranean (1915–16), he returned to France and served through the battles of the Somme in 1916, gaining two bars to his M.C. The following year saw him again on the Western front, and in the autumn he was awarded the D.S.O. for gallantry. He was gassed and slightly wounded during this campaign. In the spring of 1918 he served as M.O. to a Guards' battalion, returning to England with an injury to his wounded elbow. In June he went to join a field ambulance in Italy, remaining with it till his death. During this year he was elected a Fellow of University College for "distinction in public life." The following personal testimony from a friend may be added: "Honesty, patriotism, friendship, and love of duty were some of the simple ideals which largely made up his character, and he had a dominant but most lovable personality, which won for him a number of very devoted friends. Cool in action, he always displayed the greatest gallantry and unselfishness. Twice he was recommended for the highest decoration of all. Though several times offered staff appointments which would have carried with them promotion and comparative safety, both of which he had well earned, he preferred to remain in the line, where he seemed to bear a charmed life. In many hearts his death leaves a blank which Time can never fill."

NATIONAL BABY WEEK COUNCIL AND A MINISTRY OF HEALTH.—A conference organised by the National Baby Week Council was held at Bedford College for Women, London, on Sept. 18th, to inaugurate a propaganda campaign in support of the immediate establishment of a Ministry of Health. The desire of the council to create a strong public opinion with a view to giving speedy effect to the promised Ministry of Health Bill, led to certain speakers assuring the meeting that the country would not tolerate the opposition of private or vested interests or departmental jealousies to the immediate realisation of its demands. The following resolution was carried unanimously:—

That in view of the declared intention of the Government to introduce early in the forthcoming Session of Parliament a Ministry of Health Bill, the National Baby Week Council calls upon its members and local committees to pursue an active propaganda campaign in favour of such a Ministry so that the weight of public opinion and the support of the electorate may strengthen the hands of the Government in giving speedy effect to its intentions.

The National Baby Week Council is prepared to find speakers to address meetings on application to the secretary, 27A, Cavendish-square, London, W. 1.

THE SERVICES.

ARMY MEDICAL SERVICE.

Surg.-Gen. (ranking as Lieut.-Gen.) Sir W. L. Gubbins, K.C.B.; M.V.O., ret. pay, to be Lieutenant-General on the Retired List.

Surg.-Gens., ret. pay, to be Major-Generals on the Retired List: Sir H. R. Whitehead, K.C.B., Sir D. Bruce, K.C.B., F.R.S., Sir T. P. Woodhouse, K.C.B., R. Porter, C.B., R. H. S Sawyer, C.B., C.M.G., J. C. Culling, C.B., W. S. M. Price, Sir T. J. Gallwey, K.C.M.G., C.B., R. H. Quill, C.B., Sir G. D. Bourke, K.C.M.G., J. C Macneece, C.B., T. M. Corker, C.B., Sir R. W. Ford, K.C.M.G., C.B., D.S.O., G. J. H. Evatt, C.B., W. J. Fawcett, C.B., J. D. Edge, C.B., W. W. Kenny, C.B., P. M. Ellis, O. E. P. Lloyd, V.C., C.B.

Temp. Major-Gen. Sir G H. Makins, K.C.M.G., C.B. (Lieut.-Col., R.A.M.C. (T.F.)), relinquishes his temporary commission on re-posting, and is granted the honorary rank of Major-General

Cols. (Hon. Surg.-Gens.), ret. pay, to be honorary Major-Generals on the Retired List: Sir J. Maher, K.C.M.G., C.B., Sir M. W. Russell, K.C.M.G., C.B., R. S. F. Henderson, C.B., W. F. Stevenson, C.B., M.B., K.H.S.

ROYAL ARMY MEDICAL CORPS.

The undermentioned relinquish the acting rank of Lieutenant-Colonel on re-posting: Majors G. E. Ferguson, A. C. H. Gray, J. W. L. Scott, Capt. J. A. Andrews.

To be acting Lieutenant-Colonels (whilst in command of a Medical Unit): Majors L. V. Thurston, J. T. McEntire, W. J. Weston, Capt. R. E. Todd, Temp. Capt. (acting Major) H. Young, Temp. Major H. MacCormac (whilst specially employed).

The following relinquish the acting rank of Major on re-posting: Capts. J. J. H. Beckton, H. W. Carson, Temp. Capts. J. Rodger, J. P. Good, N. G. W. Davidson.

E. C. Hort to be temporary Major whilst specially employed.

Temp. Capt. Charles E. F. Mouat-Biggs to be temporary Major (without increased emoluments).

Temp. Capts. to be acting Majors whilst specially employed: Donald W. Roy, W. R. Wilson.

To be acting Majors: Capts. G. De la Cour, A. M. McCutcheon, R. F. O'T. Dickinson, J. James; Temp. Capts. M. J. Mottram, M. C. Gardner, C. D. Coyle, R. C. Cooke, G. Clarke, H. K. Wallace, F. B. McCarter, M. W. Littlewood, A. W. Uloth, W. W. Smith, T. O. Thompson, R. E. H. Leach.

Temp. Hon. Lieut. B. E. Hawke to be temporary Honorary Captain.

Officers relinquishing their commissions: Temp. Capts. E. H. Hamilton (on appointment under the Ministry of National Service), W. S. Pickup, J. S. Gilchrist (on account of ill-health contracted on active service, granted honorary rank of Captain), W. Hutcheson (on account of ill-health, granted the honorary rank of Captain), F. R. Snell (on account of ill-health contracted on active service, granted honorary rank of Captain), R. O. H. Jones (on account of ill-health contracted on active service, granted the honorary rank of Captain), F. A. Cooke, C. M. Bernays (on account of ill-health contracted on active service, granted the honorary rank of Captain), G. S. Robinson (on account of ill-health, granted the honorary rank of Lieutenant), J. R. White, W. Balgarnie (granted the honorary rank of Captain), (Acting Major) C. L. T. Arthur, L. E. Bolster, C. D. H. Corbett, J. M. N. S. Bickerton (on account of ill-health, granted the honorary rank of Captain), J. Craig, late temporary Captain (granted the honorary rank of Captain), E. F. Thomas, A. H. Walker; Temp. Lieuts. H. S. Mason, S. B. Depree, B. S. Cornell (on account of ill-health, granted the honorary rank of Lieutenant), C. W. S. Boggs, D. A. Tompsett, S. W. Smith (on account of ill-health), H. Cox; Temp. Hon. Lieut. C. F. Larson.

SPECIAL RESERVE OF OFFICERS.

Lieut.-Col. A. A. Watson to be acting Colonel whilst employed as Assistant Director of Medical Services of a Division.

Captains to be acting Majors: G. E. Pepper, R. Green.

Captain W. J. M. White relinquishes his commission on account of ill-health contracted on active service, and is granted the honorary rank of Captain.

Lieutenants to be Captains: D. C. Buchanan, J. Marshall, P. A. O'Brien, J. J. Robertson, R. P. Crawford, W. F. Kivlichan, J. G. McK. Macaulay, A. B. Cocker, J. B. Irving.

To be Lieutenants: E. D. D. Dickson, A. J. Meek, G. W. C. Dunlop, and H. J. Parish (from Edinburgh University Contingent O.T.C.), G. R. Ross (from St. Andrews University Contingent O.T.C.), J. Morrison (from Aberdeen University Contingent O.T.C.), R. J. Patchett.

Lieut. H. Taylor relinquishes his commission on account of ill-health, and is granted the honorary rank of Lieutenant.

TERRITORIAL FORCE.

Lieut.-Col. T. Fraser to be an Assistant Director of Medical Services and to be temporary Colonel whilst so employed.

Major J. Cumming relinquishes his commission on account of ill-health, and is granted permission to retain his rank and to wear the prescribed uniform.

Major A. R. Henchley to be acting Lieutenant-Colonel whilst specially employed.

Capt. (acting Major) B. Hughes relinquishes his acting rank.

Major F. J. Smith is retired, and is granted the honorary rank of Major.

Major (acting Lieut.-Col.) W. B. Armstrong relinquishes his acting rank on ceasing to be specially employed.

Captains to be acting Majors whilst specially employed: W. H. Morrison, C. Burrows, G. S. Melvin, F. S. Jackson, C. S. P. Black, P. S. Price, F. Scroggie, A. L. Heiser, A. W. Stott.

Captains (acting Majors) relinquishing their acting rank on ceasing to be specially employed: T. B. McKee, H. Stonehouse, D. Campbell, C. E. Petley, G. B. Pritchard, H. Duguid.

Capt. J. W. Patrick is seconded for duty with a General Hospital.

TERRITORIAL FORCE RESERVE.

Major W. A. Wetwan, from R.A.M.C., to be Major.

Capts. J. O'Sullivan and C. W. Ellison, from R.A.M.C., to be Captains.

ROYAL AIR FORCE.

Medical Branch.—H. A. Treadgold is granted a temporary commission as Captain, and to be temporary Major whilst so employed, but without the pay and allowances of that rank. S. W. Fisher is granted a temporary commission as Captain.

Dental Branch.—A. C. S. Cottam is granted a temporary commission as Lieutenant.

OVERSEA FORCES.

South African Medical Corps.—E. H. Cluver to be temporary Captain.

Medical News.

ROYAL INSTITUTE OF PUBLIC HEALTH.—A course of lectures on public health problems as they present themselves under the war, and as they may present themselves at the cessation of war, will be delivered on Wednesday afternoons at the Institute during October, November, and December, commencing on Oct. 9th, when Professor Arthur Keith will discuss Anthropometry in Relation to National Health. Among other important lectures may be mentioned those by Lieutenant-Colonel L. W. Harrison on Abortive Treatment of Venereal Disease, of Miss Jane Walker, M.D., on the Tuberculous Soldier, of Professor E. W. Hope on the Rôle of Ports in the Protection of the Health of the Nation, and of Alderman C. Spencer on the Influence of National Kitchens.

A general Order of the Local Government Board, entitled the Public Health (Tuberculosis) Regulations (No. 2), 1918, has just been issued, altering the Public Health (Tuberculosis) Regulations of 1912. The Regulations as altered apply to the notification to the proper medical officer of health by the chairman of any National Service Medical Board, or by some member of the Medical Board designated by the chairman, of every case of tuberculosis diagnosed by the Medical Board, in the same way as they apply to the notification by a medical practitioner in pursuance of Article V. of the Regulations of 1912. The fee to be paid for each notification made in pursuance of this Article will be 1*s.*, and no fee will be payable to any person who holds a commission in any of His Majesty's Forces and is receiving pay in respect thereof. This Order is to be in force during the continuation of the present war.

URBAN VITAL STATISTICS.

(Week ended Sept. 21st, 1918.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality was 11·7, against 11·9 and 11·3 per 1000 in the two preceding weeks. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 11·9, or 1·4 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 4·0 in Cambridge, 4·2 in Ilford, and 4·9 in Ealing to 17·9 in Grimsby, 18·1 in Tottenham, and 21·8 in Great Yarmouth. The principal epidemic diseases caused 389 deaths, which corresponded to an annual rate of 1·2 per 1000, and included 299 from infantile diarrhœa, 39 from diphtheria, 19 from whooping-cough, 15 from measles, 10 from scarlet fever, and 7 from enteric fever. The deaths from diarrhœa, which had declined from 435 to 346 in the three preceding weeks, further fell to 299, and included 74 in London, 20 in Liverpool, 16 in West Ham, and 13 in Sheffield. The 839 cases of scarlet fever and 1025 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 61 and 72 above the respective numbers remaining at the end of the previous week. Of the total deaths in the 96 towns 119 resulted from violence. The causes of 32 deaths were uncertified, of which 6 were registered in Birmingham and in Liverpool, and 4 in London.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,500,000 persons, the annual rate of mortality was 11·6, against 10·9 and 10·6 per 1000 in the two preceding weeks. The 274 deaths in Glasgow corresponded to an annual rate of 12·8 per 1000, and included 12 from infantile diarrhœa, 2 from whooping-cough, and 1 each from measles, scarlet fever, and diphtheria. The 75 deaths in Edinburgh were equal to a rate of 11·7 per 1000, and included a fatal case each of whooping-cough and infantile diarrhœa.

Irish Towns.—The 129 deaths in Dublin corresponded to an annual rate of 16·9, or 2·2 per 1000 below that recorded in the previous week, and included 14 from infantile diarrhœa, 2 from whooping-cough, and 1 from diphtheria. The 109 deaths in Belfast were equal to a rate of 14·5 per 1000, and included four fatal cases of infantile diarrhœa and 1 of enteric fever.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at Clitheroe.

Births, Marriages, and Deaths.

BIRTHS.

BADGEROW.—On Sept. 13th, at 2, Hill-street, Knightsbridge, the wife of Lieutenant-Colonel George W. Badgerow, C.M.G., F.R.C.S., 4, Harley-street, W.—a son.

BARTLETT.—On Sept. 15th, the wife of George Bertram Bartlett, Temporary Captain, R.A.M.C., of 21, Sutton Court, Chiswick—a son (George Adrian).

HAYLOCK.—On Sept. 22nd, at Balsham, Clifton-road, Southbourne, Bournemouth, the wife of Sydney J. Haylock, M.R.C.S. Eng., L.R.C.P. Lond., of a son.

NUTT.—On Sept. 16th, at the Highcliffe Nursing Home, Hants, the wife of Major H. R. Nutt, I.M.S., of a daughter.

ROBINSON.—On Sept. 18th, at St. Fillans, Saltash, the wife of Hugh G. Robinson, M.B., of a son.

MARRIAGES.

BRADBURY—WILLIAMS.—On Sept. 19th, at St. Swithin's, London Stone. Staff Surgeon William Bradbury, D.S.O., R.N., to Norah Michael, youngest daughter of Mr. and Mrs. G. Michael Williams, Muswell-hill, N.

GARDNER—NEWSAM.—On Sept. 18th, at St. Augustine's Church, Broxbourne, Arthur Duncan Gardner, M.D., F.R.C.S., to Violet Mary, youngest daughter of the late I. Fowler Newsam and Mrs. Fowler Newsam, of Broxbourne.

MARR—BOOKLESS.—On Sept. 20th, at the Station Hotel, Inverness, Captain David Murdoch Marr, M.B., Ch.B., R.A.M.C.S.R., to Marion Hannah Payne, youngest daughter of the late James Bookless and Mrs. Bookless, The Riggs, Inverness.

SMITH—THORNE.—On Sept. 17th, at St. Mary's, Wimbledon, John Ferguson Smith, Captain, R.A.M.C., to Ethel May Thorne.

DEATHS.

FISCHEL.—On Sept. 14th, from wounds, Captain Claude Henry Fischel, R.A.M.C., Leicesters, aged 28.

GRIFFITH.—On Sept. 24th, at The Homestead, Lingfield, Alfred Hume Griffith, M.D. Edin., D.P.H. Cantab., F.R.S.M., second son of the late Rev. Edward Moule Griffith.

HIND.—On Sept. 16th, at St. Thomas's Home, Westminster, after severe operation, Clara Hind, L.R.C.P. & S. Edin., of Ockley Sanatorium, Surrey.

JOHNSTON.—On Sept. 22nd, at a nursing home, Glasgow, Alexander Johnston, Major, R.A.M.C., M.D., D.P.H. Cantab.

MARSHALL.—On Sept. 14th, at Colaba War Hospital, Bombay, Staff Surgeon C. D. Marshall, R.N.V.R., P.M.O. in the Persian Gulf and Mesopotamia, aged 50.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

"OUR DAY."

IN consequence of the large growth of the British Armies the needs of the joint British Red Cross Society and the Order of St. John of Jerusalem in England are much greater than in any previous year. It is hoped, if sufficient help is obtained, that a new record will be created for "Our Day" Fund which is fixed for Oct. 24th next. Helpers are needed in organisation, as emblem sellers, at depôts and stalls, to call on shops and places of business, to distribute red crosses and books of stamps, as captains and teams of workers, to collect from Oct. 14th to 24th, and to pack and for general office work. Masters and mistresses of schools and children are especially invited to come in the circle for getting "miles of pennies," while any small gifts are acceptable to sell at various stalls. Anyone willing to help should communicate with Miss C. May Beeman, organising secretary, 10, West Bolton-gardens, S.W. 5.

THE DUAL PROFESSIONS.

ONE of the outstanding features of the Harvest Thanksgiving services at Giggleswick-in-Craven Church, Yorkshire, last Sunday, when the offertories were devoted to the Leeds Infirmary, was an address given, after evensong, by Dr. H. de Carle Woodcock, of Leeds, in which he pleaded for a closer alliance between the dual professions of therapeutics —viz., those of medicine and theology. He touched on the future of medical science, and stated his belief that eventually all disease would come under the Prospero spell of the physician. Whilst the State was apt to be chilling and mathematical the practice of medicine was ardent and emotional, depending on the presence of sympathy, therefore voluntary aid in our hospitals, along with individualism in private practice, would surely continue for many a long year. This was in keeping with the genius of the English character. The endowment of research was also strongly urged.

40 D.

FURTHER cases under Section 40 D, D.O.R.A. regulations have been brought before the justices at Brighton and Lewes and varying terms of imprisonment have been imposed. In a case heard at Lewes on Sept. 17th, however, the woman was discharged after evidence had been given both by a woman doctor and a bacteriologist that the results of their examinations were negative. The defending solicitor protested that it was unfair that no proceedings could be taken against the informant, and the justices agreed with the view.

THREATENED STRIKE IN AN ASYLUM.

THE attendants of the Richmond District Lunatic Asylum in Dublin last week backed up their demand for increased wages to the committee by a threat to strike if their claims were not admitted. The attendants only took this strong step in consequence of a previous request of theirs for increase of wages having been ruled out of order. It is unfortunate that any demand from an asylum staff, whether justified or not, should have been treated discourteously.

END OF SUMMER TIME.

Summer time will come to an end at 3 A.M. (summer time) on Monday next, when clocks will be put back to 2 A.M., which will be the ordinary Greenwich time.

D. M. S.—The address of the National Herb Growing Industry, Ltd., is 15, Verulam-street, E.C.; of the National Herb Federation, 29, Cockspur-street, S.W.; and of the Scottish Horticultural Association, 19, Waverley Market, Edinburgh. The Herbal Subcommittee of the Women's Farm and Garden Union, 45, Queen Anne's Chambers, London, S.W., would probably be able to give valuable information. The following books might be consulted: Ada B. Teetgen's "Profitable Herb Growing and Collecting" (office of *Country Life*, 20, Tavistock-street, W.C., price 3*s.* 6*d.*); Holmes's "Cultivation and Drying of Medicinal Plants" (E. M. Holmes, Ph.C., Ruthven, Sevenoaks, Kent, price 1*s.*); "Medicinal Herbs" (David Ellis) (Blackie and Son, Ltd., 50, Old Bailey, E.C.); Potter's "Cyclopædia of Botanical Drugs and Preparations" (edited by R. C. Wren, with additions by E. M. Holmes) (Potter and Clarke, 60, Artillery-lane, E. 1); and the pamphlets written by Mrs. Grieve, Chalfont St. Peter, Bucks; also the leaflets of the Board of Agriculture and articles in the Journal of the Board of Agriculture, to be obtained on application to the Board at 3, St. James's-square, S.W.

Medical Diary for the ensuing Week.

SOCIETIES.

PART OF

An Address

ON

SENSORY CHANGES IN THE DIAGNOSIS OF TRENCH FEVER.

Given before a Base Medical Society in France,

BY D. W. CARMALT JONES, M.D. OXON., F.R.C.P. LOND.,

MAJOR, R.A.M.C. (T.); PHYSICIAN TO WESTMINSTER HOSPITAL.

MR. PRESIDENT AND GENTLEMEN,—It has long been known that inflammation of viscera may be associated with areas of increased sensibility of the skin. This association has been investigated by many clinical workers, notably by Sir James Mackenzie and by Dr. Henry Head.

Some work has recently been done in the medical division of a base hospital in France upon the general principles laid down by these observers. It has been made a routine practice to examine the skin for hyperalgesia in internal disease of all kinds, and the records of 500 consecutive examinations are now available. Definite segmental areas of increased sensibility to pain have been found in fairly constant relation with lesions of the various viscera, as indicated by symptoms and physical signs, and certain groups of segments have been so frequently found to be hyperalgesic in cases of trench fever that their presence appears to constitute a point of considerable diagnostic value.

Some account of this method of clinical examination is here given, together with a summary of the results obtained in visceral lesions in general and in cases of trench fever in particular.

PRINCIPLE.

The work of Gaskell[1] has made it possible to construct a working hypothesis which explains the results obtained by this method of examination, and the principle adopted in present paper is this:—

The central nervous system was originally segmentally arranged, starting behind the infundibulum and reaching to the end of the body. All typical segmental nerves have four roots, afferent and efferent somatic, and afferent and efferent splanchnic. The impulses carried by the afferent splanchnic nerves, which come from the viscera, are not appreciated in consciousness; it is impossible to tell by any consciously felt sensation what is the state of activity of any viscus, for instance, whether the kidney is secreting or the intestine contracting. But when any one of the viscera is *inflamed* the impulses which pass from it by the afferent splanchnic nerves to the cord are such that they induce a state of hyperexcitability throughout the segment to which they belong, and this excitability affects especially the somatic afferent nerves. The result is this, in a case of inflammation of any viscus, a light pin-prick, insufficient to cause pain when applied to the normal skin, is resented as positively painful over the area of skin innervated from the same segment as the affected organ.

If this is true, it follows that in a given case inflammation can be diagnosed in any viscus of which the afferent nerve-supply is known by demonstrating hyperalgesia in the corresponding segmental area on the skin. To put the matter colloquially, every segment receives an afferent nerve from a viscus, and if the viscus is inflamed the skin area connected with the same segment becomes hyperalgesic. This is the principle which has guided the examinations to be described.

PRACTICE.

The practice is as follows:—

A series of light pin-pricks is applied to the skin along a line which cuts across a number of segmental areas, a line, for instance, from the clavicle to Poupart's ligament. When the pricks pass from a normal to a hyperalgesic area the patient will be seen to flinch, for this is an objective sign which depends not upon what the patient says, but upon what he is seen to do. The spot where the flinch occurs is marked with a skin-pencil, and the experiment is repeated from below upwards and the skin marked again. The observer passes both outwards and inwards from his original line, and repeats the experiment until he has mapped a complete segmental area corresponding to one or more segments. With rare exceptions a corresponding symmetrical area can be mapped on the opposite side of the body. Nothing "counts" in this method unless the whole of one or more segments can be accurately mapped out.

If, after it has been identified, a series of pricks is made within the hyperæsthetic area, and another series outside it, and the patient be asked which feels the sharpest, he will indicate the former, but the difference is rarely very great; the *edge* of the area is chiefly sensitive, so that it is the passage from the normal to the hyperalgesic that induces the characteristic flinch.

Further, within a hyperalgesic area including more than one segment, a similar flinch occurs in passing over the border between any two. Thus, when all the lumbar segments are involved, as they often are, in trench fever, a series of pricks, starting opposite the middle toe and passing up the dorsum of the foot towards the ankle, induce a flinch about half-way across the foot, on crossing from the first sacral to the fifth lumbar area. Continuing upwards along the front of the leg towards the knee another flinch will be aroused just above the ankle, where the fourth lumbar area joins the fifth, another above the knee where the third joins the fourth; and higher still on the front of the thigh will be found the lower borders of the second and first. (See Figs. 3 and 4.) Each segment can be followed right up to the middle line of the back, and it is thus possible to map each one of a series of areas in its entirety.

A suitable pricker for the purpose is a wooden match sharpened to as fine a point as possible, it should be used in the manner taught by the late Sir William Gowers; the match is held between the thumb and index finger, and the tip of the middle finger is brought alongside of the point; the prick is made with the match held vertically to the skin, and the tip of the middle finger is made to touch the skin at the same time, for when the skin is thus always felt by the finger, it is much easier to maintain a uniform pressure throughout, which is, of course, of the essence of the experiment.

A proportion of people appear to undergo no increase in sensitiveness when any of their viscera are inflamed; for instance, there are 100 negative cases in the present series of 500, and among positive cases the degree of sensibility varies very greatly, some are so sensitive that they jump all over the bed when examined; others require considerable pressure to bring out any difference. The amount of force applied must be suited to the case under examination. The pricks should be about $\frac{1}{8}$ to $\frac{1}{4}$ inch apart, and made at the rate of about ten in 5 seconds; very light pricks should be used at first and increased in force as required; an experiment on the back of one's own hand will indicate that the stimulus is a more searching one than at first sight might be expected.

GENERAL RESULTS.

The present paper is concerned more with the application of this method to trench fever than with its general utility—a few words, therefore, will suffice for the latter.

The material examined consists of about 500 consecutive patients suffering from fevers of various kinds and from disease of the circulatory, respiratory, alimentary, and genito-urinary systems.

In the course of the examinations it has been possible to map every segmental area on the surface of the body with sufficient frequency to give a fairly definite idea of the distribution of each of them, and it is possible to state with tolerable confidence that in sensitive subjects one area is associated with heart disease, another with respiratory disease, another with renal disease, and so on. One cannot say that heart disease is associated with one group and one group only, but rather that a certain large area is involved, and any given sensitive case will show hyperalgesia of some segment within that area, of which one particular series is the most frequent.

The general results obtained are summarised below, the segmental areas most frequently found hyperalgesic in inflammation of the viscera being stated. It is only a list of instances and makes no pretensions to completeness. With regard to the first two instances given, the upper nasal passages and the middle ear appear to be

[1] Gaskell: The Involuntary Nervous System.

visceral in development and possess the visceral character of exciting hyperalgesia in a segmental area of the skin when they are inflamed. They are of importance, as they then afford opportunities of mapping the distribution of the upper two divisions of the trigeminal.

Upper nasal passages: Trigeminal, upper division.	Heart: 2, 3, 4, 5 dorsal.
Middle ear: Trigeminal, middle division.	Stomach: 7, 8, 9 dorsal.
Parotid gland: Trigeminal, lower division.	Liver: 7, 8, 9 dorsal right, 7 dorsal left.
Tonsil: 2 or 3 cervical.	Small intestine: 10 dorsal.
Larynx, trachea, lungs: 4, 5, 6 C.	Kidney: 11 dorsal.
	Testis: 12 dorsal.
	Large intestine: 1, 2, 3, 4, 5 sacral

It will be seen that, if these observations are correct, this method of examination supplies a considerable addition to the ordinary means of diagnosis.

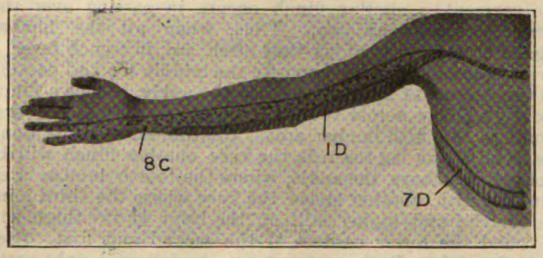

FIG. 1.—Upper and middle groups, anterior view.

In these figures the hyperalgesic areas were mapped in the manner described in the text; the outline of each segment was marked on the skin with grease-paint and the patient was photographed. The areas have been shaded-in on the prints, alternate segments being distinguished by bars and dots. The figures show the three groups of hyperalgesic segments of the "full trench-fever" distribution. Photographed by Captain C. H. Hopwood, R.A.M.C.

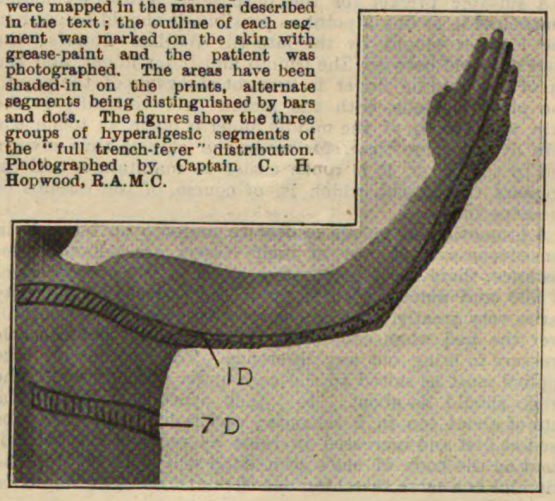

FIG. 2.—Upper and middle groups, posterior view.

RESULTS IN TRENCH FEVER.

Among the patients examined in this series were about 130 cases of "fever" of various kinds, including trench fever, malaria, cerebro-spinal meningitis, scarlet fever, measles, rose measles, mumps, diphtheria, and surgical septicæmia. Of these, trench fever and malaria were commonly associated with hyperalgesia of three definite groups of segments which do not correspond with those belonging to any of the viscera enumerated above.

In no other fever was anything of this kind found; cases in which there were clear symptoms or physical signs pointing to inflammation of any viscus often showed hyperalgesia over the appropriate segments, but that was all. The parotitis of mumps, the bronchitis of measles and the nephritis of scarlet fever all showed typical areas, and throughout the fevers, in cases of severity the eleventh dorsal area, corresponding to the kidney, was often hypersensitive, and when this was so albumin was nearly always to be found in the urine; this is especially true of surgical septicæmia. The inference is that the kidney suffers damage in the process of eliminating bacteria and their toxins.

But hyperalgesic areas of unexplained origin were found only in trench fever and malaria. In these fevers the following were found: the eighth cervical and first dorsal, the seventh dorsal, and the first, second, third, fourth, and fifth lumbar. This is the "full trench fever distribution," and is found frequently in its entirety, and in nearly every case which is diagnosed as trench fever on clinical grounds this distribution is to be found more or less complete.

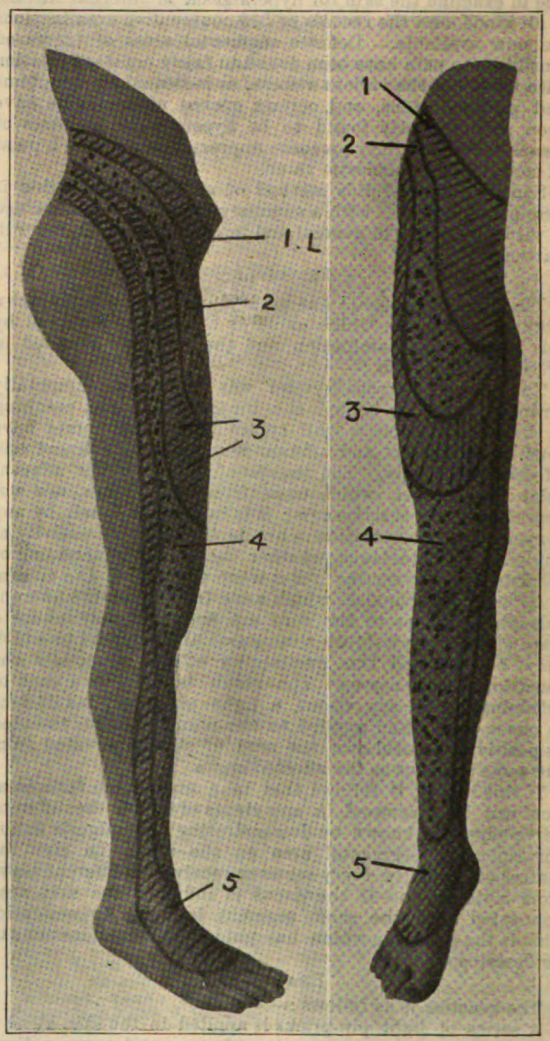
In this series 73 cases of trench fever have been examined, and in the following table are set out the segmental areas of hyperalgesia found:—

Upper Group—		Lower Group—	
8 C., 1 D.	29 } 39	1, 2, 3, 4, 5 L.	57 } 67
1 D. (alone)	10 }	Incomplete lumbar ...	10 }
Middle Group—		"Full Trench Fever"—	
7 D. (alone)	55 } 68	8 C., 1 D.; 7 D.; 1, 2, 3, 4, 5 L.	24
7 D. + adjacent areas ...	13 }	Nil	5

Eighteen cases of malaria were examined, of which 16 showed precisely similar areas to those found in trench fever. In no other fever was this the case.

CONCLUSION.

It is suggested, therefore, that hyperalgesia of these particular segments is diagnostic of a group of diseases consisting of malaria and trench fever, and it is remarkable that one of them is mosquito-borne and the other louse-borne; that both appear to be protozoal, with a definite



FIGS. 3 and 4.—Lower group, lateral and anterior views.

cycle of development, as shown by the periodicity of the febrile attacks induced by them; that both appear to lie dormant for considerable periods within the body; and that both are associated with enlargement of the spleen.

These hyperalgesiæ are precisely similar to those found in inflammation of the viscera, but it is difficult to see to

what viscera they can correspond, though a few possibilities suggest themselves.

The eighth cervical and first dorsal areas perhaps indicate an affection of the thyroid gland; no opportunity has recently arisen of examining a case of Graves's disease, but a case of acute thyroiditis lately examined showed some hyperalgesia of the first dorsal.

The seventh dorsal area may possibly indicate the spleen, which is enlarged in both the diseases concerned, or else the suprarenal gland, since there is evidence of increased excitability of the sympathetic in trench fever, as has been pointed out by Major H. F. Marris, R.A.M.C. Also the physiological association between thyroid and suprarenal should be borne in mind. Cases of Addison's disease and of splenitis from any cause would go far to elucidate this point.

The cause of hyperalgesia of the lumbar segments is quite obscure; it does not appear to be any condition of the small intestine, kidney, testis or large intestine, and it is difficult to see what remains. In the only two cases of cystitis so far examined some lumbar segments were found involved, in one of them the first three, but the absence of symptoms pointing to any vesical disturbance makes such a view difficult to accept; at present it must be said that the significance of a lumbar hyperalgesia in these diseases is unexplained.

VALUE IN DIAGNOSIS.

Anyone who systematically investigates the skin sensibility in trench fever will hardly fail to be struck with the frequent occurrence of these hyperalgesic areas. The writer regards them as diagnostic when malaria can be excluded. These particular areas are demonstrable in so many cases of typical trench fever that it is not a very long shot to suggest that afebrile cases of other disorders, such as D.A.H. and debility, which show the same changes, are suffering from a chronic form of the same infection, if there has been a reasonable chance of exposure. It is certainly the case that a large proportion of patients in military hospitals who have served for such a period as two years in France, and who show the familiar signs of exhaustion, give this evidence of trench fever infection, and trench fever thus appears responsible for a very serious amount of military wastage.

For instance, among 100 cases of D.A.H. examined at a "heart centre" in France, who showed positive changes in sensibility, 67 gave evidence pointing to trench fever alone, and 33 had signs of a true heart lesion, and of the latter 22 showed signs of trench fever in addition. Assuming these signs to be trustworthy, they mean that among 100 cases of D.A.H. taken at random and serious enough to reach a heart centre, two out of three were due to trench fever alone, and eight out of nine were due to this infection, at least in part.

If this is true, or anything like true, it is a very serious indictment of trench fever as a source of invaliding. It is believed that such cases can be picked out when required by a systematic examination of the sensibility of the skin.

The existence of bilateral hyperalgesia of the skin in trench fever has already been pointed out by Major Marris, to whom the writer's thanks are due for his first introduction to that phenomenon. His thanks are also due to Lieutenant-Colonel J. S. Warrack, R.A.M.C., commanding an infectious compound, for his kindness in allowing the examination of cases of the acute fever, and in special degree to his colleague, Captain C. E. Pepper, R.A.M.C., for continuous help and suggestion.

In conclusion, it is obvious that the material examined is insufficient to admit of any final and dogmatic assertion as to the pathognomonic character of the hyperalgesic areas described in trench fever, but they are found so frequently, and the experiment is so striking, that the phenomenon seems to be worth bringing to the notice of those interested for more extended investigation.

INFLUENZA IN INDIA.—There has been a widespread epidemic of influenza throughout India, introduced, the medical officers of health agree, through shipping. The health officer of the Calcutta Corporation has issued a leaflet containing simple rules to be observed: (1) Avoid unnecessary exposure and fatigue; (2) do not travel in overcrowded tramcars; (3) do not visit overcrowded places of public resort; (4) do not neglect apparently trifling symptoms of ill-health; (5) if attacked, go to bed and stay there until your doctor allows you to get up; (6) the first case in a house should be isolated, the sputum (if any) disinfected, handkerchiefs, &c., boiled.

THE PATHOLOGICAL DIAGNOSIS IN GUNSHOT INJURIES OF PERIPHERAL NERVES.

BY JOHN S. B. STOPFORD, M.D. MANCH.,
LECTURER IN ANATOMY, UNIVERSITY OF MANCHESTER.

(Report to the Medical Research Committee.)

IT is rarely difficult to make an anatomical diagnosis in peripheral nerve injuries except in a few of the complex lesions of the brachial plexus, but in order to estimate the prognosis or advise the correct line of treatment—other than the routine postural and nutritional treatment of the paralysed or paretic muscles—it is necessary also to be able to diagnose as accurately as possible the pathological condition of the nerve at the site of the injury. This is always a difficult problem to solve with certainty, but observations made before and after operations, when it is practicable to make a fairly trustworthy examination of the nerve at the point of injury, have enabled us to recognise certain signs and symptoms as indicative of the various conditions. In some cases only a speculative opinion can be given, but the manifestations discussed in this paper are put forward with the intention of promoting a better recognition of the various complications and are the result of observations made on more than 2000 patients.

Nature of Injury.

The initial injury may be:—

(i.) So-called *concussion*, in which no nerve fibres are divided, but there is a temporary loss of conduction.
(ii.) *Partial division*, in which the missile either divides a variable number of the more peripheral fibres or, in the case of large nerves like the sciatic, passes through the trunk, severing the central fibres. In either instance the division is incomplete.
(iii.) *Complete anatomical division.*

(i.) In concussion a satisfactory recovery occurs usually within three or four months, unless compression by the neighbouring scar tissue supervenes.

(ii.) In partial division the extent of recovery will depend upon the number of fibres divided and the character and extent of the scar in the vicinity.

(*a*) When very few fibres have been lacerated a good functional result may be anticipated, provided the scar causes no complications.

(*b*) When a large number of fibres have been severed the ultimate recovery will be incomplete without surgical intervention. The recovery of function will depend also upon which fibres have been injured most seriously, since a considerable functional disability must follow an injury which involves chiefly motor fibres. The regenerating fibrils will form a neuromatous bulb, and on account of the close proximity of the scar there must be inevitably a constant risk of implication of the intact fibres by it. The perineural scar may cause compression and the intraneural fibrosis is most likely to give rise to irritation, both complications being frequently associated in such cases. In severe forms the perineural or intraneural scars, or both combined, finally may destroy completely all conduction in the undivided fibres, and the clinical condition then becomes that of complete division; this is particularly probable when the missile has traversed the centre of the nerve.

Compression necessarily disturbs the blood-supply of a nerve, and may in this way itself lead to symptoms of irritation.

Consequently, in partial division the recovery may be almost perfect, incomplete, or complicated by compression, irritation, or both.

(iii.) In complete anatomical division no recovery is to be expected without suture of the nerve, but it is important to remember that the regeneration at the extremity of the proximal end will produce an end bulb and the growing fibrils will ramify widely in the surrounding tissues. It has been shown already that complete loss of conduction may succeed concussion or partial division (being the result of strangulation by the perineural scar or conversion of the injured segment into a fibrotic cord), as well as complete anatomical division.

Scheme of Examination.

At the outset, whatever the initial injury may be, the loss of conduction is profound, and it is rarely possible at an

early date to estimate with any degree of accuracy the precise extent of the damage; nor is it practicable, for this reason and because of the possibility of compression or irritation subsequently, to give a prognosis at this time. The necessary delay in determining the pathological diagnosis is really of slight disadvantage, since the condition of the wound rarely permits any special treatment being adopted. During this time the affected muscles are constantly supported by suitable appliances, and their nutrition and the mobility of joints maintained as well as possible by massage, rhythmical electrical stimulation, and passive movements. Throughout this time the patient ought to be systematically examined at regular intervals in order to observe any motor, sensory, or trophic changes which may lead to the establishment of a correct pathological diagnosis.

A useful scheme of examination for routine work is the following:—

1. *History.*—Inquiry should be made as to the condition at the time of injury and the presence or absence of any special subjective symptoms. The treatment previously given and the history of recovery or relapse should also be noted. Attention must not only be paid to operations on nerves, but also to ligature of any of the main blood-vessels. The time of onset of the paralytic or sensory symptoms is also important, as in cases of pure compression it may be delayed until the wound heals.

2. *Mobility.*—It is necessary to test the range of passive movement at all the joints in the region of the disability; this will demonstrate the presence of muscular or fibrous contractures and arthritic adhesions, and thus not only prevents mechanical limitation of movement being mistaken for muscle weakness of nervous origin, but also manifests changes due to nerve irritation or ischæmia.

3. *Motor.*—The range and power of voluntary contraction of all the muscles of the affected limb must be examined, and the condition and tone of any paretic or paralysed groups noted. It is scarcely necessary to emphasise the care required in testing movements of certain individual muscles of the hand, such as the abductor brevis pollicis or the interossei. At this stage any electrical tests may be performed, which examination is also of service in helping to recognise functional loss of power, a complication not infrequently found in the presence of nerve irritation.[1]

4. *Sensory.*—An accurate knowledge of the subjective sensory troubles is of great diagnostic value, and therefore it is useful to make a careful inquiry into any form of pain or similar manifestation. After testing the objective sensory disturbances they should be charted for comparison of findings at subsequent examinations; to prevent error the examinations of cutaneous sensation should, as far as possible, be carried out under the same conditions, since variations in temperature may materially modify sensibility.

5. *Trophic.*—The localisation of any abnormal vaso-motor state and the appearance of the skin supplied by the affected nerve are of great service. The surface temperature of the skin is lowered in complete division and commonly raised in irritation. The presence of more obvious conditions, as "glossy" skin, ridging of the nails, arthritic changes, hyperidrosis, œdema, loss of hair, and trophic sores, are less likely to pass unobserved.

6. *Palpation of the nerve.*—This is a most useful procedure and must be done not only at the site of the injury, but also along the full course of the nerve distal to this point, and any subjective experience resulting from it noted. Great significance has been given to the diagnostic value of this examination, but it seems clear that considerable experience and judgment is required in order to interpret correctly the results.

Concussion.

In uncomplicated concussion recovery usually commences within two to four weeks in both sensory and motor fibres, the very earliest change being commonly found in a concomitant recession of the anæsthesia and analgesia proximally.

The muscles rarely show any advanced wasting, and it is uncommon to discover any extensive loss of deep sensibility; if this has temporarily disappeared, it generally returns at an early date. Consequently, very early indications of recovery with only slight atrophy of muscles and no loss, or rapid return, of deep sensibility may be considered as evidence of concussion. Unless some complication arises patients suffering from concussion show spontaneous, rapid, and complete recovery often before the wound has healed, at which time there is still a risk of compression occurring.

Compression.

This is the usual cause of delayed involvement of nerves or may complicate concussion or partial division, but its manifestations are only to be expected when the wound has healed and the scar contracts. Consequently, the onset of paralytic or sensory symptoms during convalescence, the sudden cessation of recovery, or a relapse would suggest its presence.

A prominent symptom often marking the onset is the appearance of pain of a neuralgic type along the course of the nerve, the pain being commonly induced by movement or stretching of the nerve trunk. Pain caused by a movement which stretches the nerve is very suggestive of perineural adhesions. A peculiar sensory dissociation, in which the analgesia to the prick of a pin is more extensive than the anæsthesia to the lightest application of a small camel hair-brush, has been described in a previous paper as a characteristic phenomenon in compression.[2]

There is a tendency for the compression to become progressively worse and, in the most severe types, it may proceed to strangulation of the nerve and complete loss of conduction.

Irritation.

This complication is found most frequently in cases of incomplete anatomical division and is often associated with compression.

In rare circumstances clinical manifestations of irritation are found, but at operation it is discovered that the missile has passed close to the nerve without lacerating any fibres, and the resultant scar has not implicated in any way the nerve. It seems probable, from the histological examination of excised portions of nerve in such cases, that minute hæmorrhages from ruptured vasa nervorum with their subsequent replacement by granulation tissue are responsible for the irritation. Therefore it seems possible that occasionally concussion, in which small intraneural hæmorrhages have occurred, may be complicated by symptoms of irritation.

Perineural adhesions alone, apparently by disturbing the blood-supply of the nerve, occasionally also cause mild symptoms of irritation.

The onset of irritation is usually early, within the first ten days when produced by the initial hæmorrhage, but it may be delayed until such time as the scar begins to invade the intact fibres. The clinical manifestations of irritation are numerous, but only a certain proportion are to be expected in any one case. The clearest manifestations are found in irritation of nerves containing a large proportion of sympathetic fibres, as the median, sciatic or its principal branches, and the ulnar.

Pain is the most constant and frequently the most predominant symptom, but it differs in character, situation, and in certain other ways from that found in compression. It is described as "burning," "pricking," or even "stinging" in character, is experienced in the sensory distribution of the affected nerve, and is influenced markedly by variations in temperature. Patients showing the dual complication of irritation and compression generally give quite a clear and distinct account of the two types of pain they experience, that indicating irritation differing completely from the neuralgia of compression.

The other signs are the trophic changes, the presence of which always denotes irritation or ischæmia from occlusion of one of the principal arteries. They vary in different cases both in extent and character, since they depend upon the site and seriousness of the laceration and source of irritation. When only a few fibres have been divided a petechial or herpetiform eruption in the sensory field of the nerve is sometimes observed, but a more frequent occurrence is hyperæmia of the skin, generally with definitely increased surface temperature, hyperidrosis, and œdema. In almost all there is hyperalgesia, often very intense, to the slightest pressure over part or the whole of the skin supplied by the nerve. Later the more serious manifestations occur, represented by trophic sores, "glossy" skin, "ridging" of the nails, loss of hair, localised osteoporosis, and fibrous contractures of muscles supplied by the injured nerve.

Palpation of the nerve shows it to be exquisitely tender, not only at the site of laceration but distally, and slight compression of its trunk below the injury (where it can often be felt to be swollen) causes severe pain, usually radiating along the course of the nerve. The results of palpation are particularly useful signs of irritation, although tenderness of the nerve trunk distally is not in itself reliable and must not be confused with a similar manifestation found in regeneration.[3] From personal experience the tenderness found in irritation tends to be much more acute and intense than that seen in cases of regeneration.

Partial Division.

This condition is found rarely uncomplicated by irritation or compression.

A point in the history which often proves of some help is the memory of an agonising pain, like a very severe electric shock, striking down the limb at the moment of being wounded. This does not occur commonly in concussion, but there may be such a history in complete anatomical division.

As in the other forms the symptoms at first are profound, and recovery does not commence until a later date than in concussion, generally from 8 to 12 weeks after the reception of the wound. The slighter the laceration, of course, the earlier improvement is likely to occur.

The first sign of recovery is usually seen in the sensory fibres, but if these have been damaged most severely the earliest change will be a return of tone in some of the muscles, followed at a later date by slight voluntary movement.

So far the only helpful points in the differential diagnosis between partial division and concussion have been the history at the moment of injury and the tendency for the more profound symptoms to persist and definite signs of recovery to be delayed in the former.

After about five or six weeks palpation of the nerve at the site of the injury offers further help. In partial division definite and localised tenderness will be discovered, unless no sensory fibres have been injured, and the pain generally radiates distally along the nerve on compression being applied by the finger in this region. This pain is the result of stimulation of the regenerating sensory fibrils which have invaded the surrounding scar and tissues, and is often referred to some part of the anæsthetic skin. When the nerve is fairly superficial the sensitive neuroma may be recognised frequently by palpation, but it must be remembered that a tender and palpable neuroma may be found in complete division.

In partial division the recovery tends to progress more slowly than in concussion. The functional result and extent of recovery in uncomplicated cases of partial division will depend upon the number and type of fibres severed. This can only be judged when all improvement has definitely ceased unless the nerve is explored surgically, a procedure which is clearly inadvisable as long as recovery is maintained and no complication occurs.

Complete Division.

In this lesion the signs of division from the first will remain profound, unless the nerve is sutured.

There is complete paralysis with marked atrophy of all the muscles supplied by the nerve below the injury, and full and persistent loss of conduction in the sensory and sympathetic fibres. The complete loss of tone in the paralysed muscles may be of some diagnostic value, since retention of some tone is frequently found in concussion and compression and occasionally in irritation and partial division.

The sensory dissociation is that of complete interruption —i.e., the anæsthesia to the lightest form of touch is more extensive than the analgesia to pin-prick, and the loss of deep sensibility is extensive in most cases. The sensory loss in compression, irritation, and partial division is apt to vary from time to time, but never in complete division if the examination is accurately performed.

The anæsthetic skin is dry, inelastic, and the surface desquamation delayed. The capillary circulation is sluggish, giving rise to hypothermia, and the area of skin corresponding to the loss of protopathic sensibility is of a deeper red colour than normal, with a cyanotic tinge, but this colour may be obscured by the accumulation of superficial scales. On palpation the dryness and loss of elasticity of the skin are shown in marked contrast with the normal.

The absence of true trophic lesions is of great service in distinguishing complete from incomplete division.

After the elapse of some weeks the bulb on the extremity of the proximal end may be felt, and compression of it cause pain referred to the distal part of the limb, but care must be taken not to interpret this in the absence of any sign of conduction in the motor, sensory, or sympathetic fibres as an indication of partial division.

Electrical Reactions.

No reference has been made previously to electrical reactions, since they do not appear to be of any great service in determining the pathological diagnosis. It has been quite a common experience to find recovery of voluntary power in muscles which fail to respond to faradic stimulation.

My investigations have had to be undertaken without the use of the condenser current, but it seems from the experiences of others to be of assistance in discovering the early recovery of conduction of motor fibres before the return of any voluntary movement.

A comparison of the response to faradic stimulation of the nerve above and below the site of the lesion is useful in estimating the severity of the injury, but retention of irritability in the distal part of its course with loss of conduction at the point of injury does not appear to be an infallible sign of concussion or compression. In simple concussion the faradic response is rarely lost in the muscles.

The surgeon must be familiar with cases which clinically manifest signs of irritation, but at operation the nerve is found to be quite free and no intraneural thickening can be palpated. Direct faradic stimulation of the nerve at the operation will show generally severe obstruction. In such cases where I have been able to examine microscopically excised portions of the nerve an intraneural fibrosis has been found, which, I venture to suggest, is secondary to hæmorrhages from rupture of the vasa nervorum by the divulsive force of the missile as it traverses the structures in the vicinity of the nerve.

Regeneration.

The evidences of regeneration in the various forms of injury have been briefly alluded to, but it is also of importance to be able to recognise correctly early indications of recovery after such operations as suture and neurolysis.

In the former Head, Rivers, and Sherren [4] found a return of cutaneous sensibility to pain commenced early after division and primary suture of a sensory nerve, but from observations in gunshot injuries of mixed nerves it appears that this does not occur at all constantly after *secondary* suture.

From personal observations it seems to be a test of perfect technique and coaptation of the two ends without distortion of the nerve bundles. In large nerve trunks it can be imagined such perfection is difficult to procure, and scarcely to be expected in secondary suture when a considerable portion of the nerve trunk has been excised.

It is found that after secondary suture in gunshot injuries the early signs of recovery appear to vary considerably. In small nerves, and when the ends have been brought into perfect apposition, recovery of protopathic sensibility first seems to be the rule, and with it regeneration of the sympathetic fibres.

An indication which is even easier to discover, and found frequently as early as the sixth week after secondary suture of a mixed nerve, is the subjective sensation of "stinging" in the sensory field of the nerve on palpation of the trunk a little distal to the site of suture.

Care must be taken not to confuse tenderness of the end bulb after an unsatisfactory operation, and when there is any doubt it is preferable to delay giving an opinion until sufficient time has elapsed to see if the stinging can be induced by digital compression of the nerve at a more distal point than at the previous examination. It is very frequently necessary to take this precaution, since in complete division the young fibrils growing out from the proximal end ramify very widely in the surrounding tissues.

Tinel [5] considers this one of the most useful signs of regeneration, but it must be realised that regeneration can occur without the presence of this phenomenon. I have noticed the absence of this sign most frequently after secondary suture of the musculo-spiral (a nerve largely composed of motor fibres), when the functional recovery has been good but there has been no improvement in sensation.

From a series of cases of regeneration without occurrence of this indication it seems fairly clear that its presence is due to slight irritation of the regenerating sensory fibres, and that it is undoubtedly evidence of active regeneration, but only gives definite information about the afferent fibres. The subjective manifestations, as radiating pains, which are fairly frequently complained of whilst regeneration is proceeding, are probably produced in a similar way as a result of compression of the growing fibrils by movement or contraction of adjacent muscles.

Another sign emphasised by Benisty [6] is the appearance of radiating diffuse pain on pinching the skin supplied by the regenerating nerve. This is also a manifestation of regeneration of afferent fibres, and, furthermore, does not appear to be of any great practical value, since its occurrence is irregular, and, as is to be anticipated, its appearance much later than the subjective symptoms produced by palpation of the nerve trunk.

It does not seem possible to formulate any rules about the further signs or rate of recovery after secondary suture, nor is it to be expected when it is realised that so very many factors influence the regeneration.

Not only do the extent of the excised piece of nerve and the perfection of the operative technique affect the recovery, but it has been found also that the various nerves behave in a different manner after suture. The usually highly satisfactory functional result following secondary suture of the musculo-spiral depends probably upon the larger proportion

of motor fibres and the consequent increased possibility of motor bundles in the proximal end coming into relation with degenerate motor bundles in the distal end.

The result of our experience so far seems to point to the fact that nerves can regenerate much more quickly than was anticipated if they are placed under the most favourable circumstances for the correct performance of this function. They are always willing, apparently, to regenerate, but the trouble is to prevent any obstruction to their growth into their normal physiological paths.

After neurolysis, in cases where there is no intraneural complication or serious division of fibres, there is usually a rapid improvement in both motor and sensory fibres, unless the constriction has been very severe, since in the worst forms it may lead to complete local destruction of the whole nerve. The recovery is often first manifested by the motor fibres; but complete recovery, on the other hand, of the sensory fibres is found commonly before function is perfect, the delay in recovery of function being most probably of muscle rather than nervous origin.

The Effect of Ligature of the Principal Arteries.

It is not intended to discuss the well-known ischæmic disabilities which may be mistaken for those of nervous origin, but only to refer to the modification of the clinical picture which the complications of arterial obstruction may produce in injuries of the peripheral nerves.

Ligature of one of the main vessels of the forearm or leg does not appear to have any obvious effect either on the symptomatology or prognosis, but occlusion at a higher level usually exerts some influence, although a fair proportion in which the brachial artery has been ligatured just proximal to the elbow have failed to show any modification of importance which could be ascribed to the arterial complication. This is probably because the patients are chiefly young subjects, free from any arterial disease, and the collateral circulation in this locality is so perfect.

Arterial obstruction in the proximal part of the limb tends to exaggerate the trophic disturbances, but careful examination will show that such symptoms as cyanosis and hypothermia involve the whole hand or foot and do not correspond to the distribution of any peripheral nerve. Trophic sores are more likely to occur, and this predominance of trophic manifestations in nerve injuries complicated by arterial lesions makes the symptoms of irritation often difficult to interpret. It is in these cases that tenderness of the nerve trunk is of special value as evidence of the presence of nerve irritation, since the trophic disturbances cannot be considered with certainty as nervous in origin. The difficulty is intensified in late cases of irritation when secondary vascular changes may supervene as a result of the persistent and long-continued irritation.[7]

Arthritic adhesions and fibrous contractures of the muscles are particularly frequent after ligature of the large arteries in the proximal part of the limbs, as the axillary or femoral, but their widespread distribution rather than localisation to the distribution of any nerve generally suggests their correct etiology.

As can be expected, arterial complications seriously affect the prognosis; occlusion of main vessels almost invariably delays recovery and renders the ultimate result less perfect.

Sources of Error.

The most striking illustrations of the points of importance in the differential diagnosis of the various lesions of the peripheral nerves after gunshot injuries may be seen in brachial plexus cases, where in the same arm signs of concussion, complete division, and irritation may all be manifested.

The signs and symptoms described in this paper have been tested during the past three years, and from this experience it seems possible to formulate an accurate pathological diagnosis in almost 90 per cent. of cases; but it must be fully understood that this cannot be done during the first few weeks after injury, when the manifestations are almost invariably profound.

Error has occurred most frequently from too much reliance being placed on the result of palpation of the nerve. On several occasions partial division has been diagnosed because the nerve trunk distal to the point of injury was tender, although all the other symptoms pointed to complete loss of conduction, and at operation complete anatomical division has been found. Consequently tenderness of the nerve below the lesion *alone* cannot be regarded as a reliable sign of partial division, although it is difficult to understand the phenomenon in complete division unless it is explained by the presence of a communication with an intact nerve below the point of injury.

Another risk of error arises from palpation of the end bulb in complete division, as the referred pain arising from manipulation of it is liable to be interpreted as evidence of incomplete division.

A third point of difficulty arises in cases of severe intraneural sclerosis, where the scar has first caused irritation and later complete obstruction to conduction. If the patient is seen first at the latter time certain signs of irritation may persist, although a thorough investigation will demonstrate that there is really a complete loss of conduction. Furthermore, it has been previously noted that trophic lesions may be maintained by endarteritis, the result of continued nerve irritation.

In conclusion, I desire to express my deepest thanks to the members of the surgical staff of the 2nd Western General Hospital for the assistance they have always so willingly given in ascertaining for me the precise conditions found at operation, and for providing me with excised portions of nerves to make histological examinations.

REPORTS FROM THE PATHOLOGICAL LABORATORIES

OF NO. —— GENERAL HOSPITAL, ALEXANDRIA.

BY J. GORDON THOMSON, M.B., CH.B. EDIN.,
CAPTAIN, R.A.M.C. (T.C.); PATHOLOGIST TO —— GENERAL HOSPITAL; PROTOZOOLOGIST TO LONDON SCHOOL OF TROPICAL MEDICINE;
AND
L. F. HIRST, M.D., B.S. LOND., D.P.H.,
CAPTAIN, R.A.M.C. (T.C.); PATHOLOGIST TO —— GENERAL HOSPITAL; BACTERIOLOGIST TO CITY OF COLOMBO.

Introductory Note.

THE following are a continuation of abridged reports on work done in the Pathological Laboratories of No. —— General Hospital, Alexandria, during the period 1916–17 on the subjects specified and by the respective authors named at the head of each report. Nos. I. and II. were published in THE LANCET of April 20th, 1918.

III.—MACROSCOPIC AND MICROSCOPIC METHODS OF DIAGNOSING AMŒBIC AND BACILLARY DYSENTERY.

By Captain THOMSON and Captain HIRST.

Every stool is sent entire to the laboratory for examination and not a small portion of it. For this purpose a special fly-proof room for the bed-pans is set apart. The examination of the stools macroscopically and microscopically is of great value as an indicator of the condition of the intestine. A clinician with considerable experience who has carefully coördinated his observations with the pathological findings will arrive in nearly every case at a correct diagnosis by this method alone, especially when he combines his experience with the clinical picture of the patient under his charge.

In acute bacillary dysentery we find very frequently a stool with clear mucus like white currant jelly stained with streaks of bright red blood. Often there is no fæcal matter. When examined microscopically the cell picture is composed of numerous pus cells and degenerate epithelial cells often rounded up and showing pyknosis of the nuclear chromatin. The large degenerate cells must not be mistaken for amœbæ.

The choleraic type of bacillary dysentery has quite a different appearance. The stool in these cases is very fluid and may be brown, straw-coloured, or greenish in tint and is filled with flakes of white mucous shreds. The cell picture is again characterised by the large number of pus cells and degenerate epithelial cells in the field of the microscope, and in these cases it is necessary to exclude cholera vibrios.

Another type of bacillary stool is characterised by the presence of small pieces of necrotic mucosa, giving the appearance of minced-up mucous membrane and like meat-

washings. This stool is a very common one in severe epidemics. It shows that considerable damage has occurred and that the mucous membrane is stripping off from the deeper layers of the gut wall.

We have a less common occurrence in acute bacillary dysentery—namely, the passage of casts of portions of the mucosa of the large intestine. We had three such cases here during the year 1916; and in some cases we have large casts of blood passed which simulate true casts of the intestine, but which are composed only of clotted blood and fibrine.

Amœbic dysentery when pure, without secondary infection of dysentery bacilli or atypical organisms, has a very characteristic macroscopic appearance. The mucus is more or less stained dark brown or chocolate colour—that is, the blood is broken down and not the bright red of acute bacillary dysentery. Examined under the microscope, such a stool shows a field very poor in cellular elements, and the red blood cells are mostly broken down. A very common feature of these amœbic stools is the presence of Charcot-Leyden crystals caused by the breaking down of the red cells by the action of the entamœbæ. Charcot-Leyden crystals, although not pathognomonic of amœbic dysentery, are, in our experience, very suggestive of the condition, and we have noted their frequency in cases of cyst carriers with no obvious blood in the stools.

Another characteristic of amœbic dysentery to the naked eye is what is called the "sago-grain" stool, caused by the mucus occurring in little clear masses or clumps mixed with dark stained chocolate-coloured material. The macroscopic diagnosis is definite if entamœbæ are present which show ingested red blood cells.

The above description more or less describes the common conditions met with in cases of amœbic and bacillary dysentery. In chronic cases of dysentery, both bacillary and amœbic, and during recovery from these conditions we find patients continue to pass mucus either in clumps or mixed up with a fluid fæcal stool.

Sometimes this is clear viscid mucus, frequently it is pure pus, and very often the mucus is white, opaque, and very viscid. It may occur as a clump or it may be noted as small flakes on the surface of a solid fæcal mass. Patients who seem otherwise well often have these conditions indicative of some past dysenteric attack, and the condition is popularly known as "colitis." Frequently the cell picture of these cases is comprised chiefly of columnar epithelial cells.

The question arises as to whether many cases of amœbic dysentery are missed by failing to find entamœbæ. We do not think a large percentage are, if the pathologist is experienced in the work, but certainly some cases are missed, especially in cases which are complicated by an acute bacillary dysentery where the amœbic condition is masked owing to the great outpouring of blood and muco-pus. After the bacillary condition has abated these cases may be discovered by a further microscopic examination. The rapid diagnosis of bacillary dysentery is of great importance so that the specific treatment can be administered at once. Willmore and Shearman (1915), working in this hospital, showed that the cell pictures of amœbic and bacillary dysentery were characteristic. A pure amœbic infection has very few cells in the field and pus cells are scarce. In the acute bacillary cases we have a field packed with pus cells, red cells, and degenerate epithelial cells and no entamœbæ present.

The report of this condition is sent at once to the physician in charge with a note that the cell picture is suggestive of bacillary dysentery, and if the case is urgent serum is administered at once, there being no necessity to wait 48 hours for the bacteriological report.

IV.—TYPES OF DYSENTERY BACILLI ISOLATED.

By the same Authors.

During the year 1916 a total of 123 strains of dysentery bacilli were isolated from 331 specimens; Shiga Kruse type 43, Flexner Y type 51, atypical 29, mixed amœbic 19. For the first six months of 1917 the corresponding figures are 51 strains, 406 specimens; 8 Shiga Kruse, 14 Flexner Y type, 29 atypical, and 2 mixed amœbic.

Nearly all the specimens plated for diagnosis during 1916 were acute type, blood and mucus stools. For various reasons a large proportion of the acute stools were not plated during the earlier part of 1916, the distinction between bacillary and amœbic dysentery being made on the basis of the microscopical examination and clinical picture of the case.

During the first half of 1917 a greatly increased number of the fæcal stools of convalescent dysentery patients have been examined. Thus only 67 out of the total were acute type stools, and 37 subacute, and 302 fæcal. Twenty-two strains were isolated from the blood and mucus acute type stools, 18 from the subacute, 11 from the fæcal type.

Since the present register of dysentery bacilli was started on Sept. 1st, 1916, 115 strains have been isolated from 104 cases by one of us (L. F. H.).

The same organisms have been isolated on six separate occasions from one case; in several instances on a second occasion during a relapse. In one case an atypical Shiga type organism was isolated during the first attack, and a typical Flexner bacillus eight weeks later. A typical agglutinating Shiga and a typical Flexner were isolated from one case on successive days from the same attack.

As a rule it was only practicable to put one of the provisional positive glucose tubes through all the tests; if more of these had been examined, doubtless more cases of mixed bacillary infection would have been discovered.

Table I. summarises the characters of the first 100 strains isolated from as many soldiers. Thus, there were 29 strains of typical *B. dysenteriæ* (Shiga) and 32 strains of *B. dysenteriæ* (Flexner) and 39 atypical strains. Representative strains of each of the types isolated have been kept alive by subculture for five months after being first replated to ensure purity; the fermentation reactions and agglutinability were then re-tested.

TABLE I.—*Showing the Characters of 100 Strains Isolated from the Same Number of Soldiers.*

Type No.	Total Nos. of each strain.	Principal biochemical characters									Remarks.	Species group.
		Motility.	Lactose.	Glucose.	Mannite.	Maltose.	Saccharose.	Dulcite.	Indol.	Shiga serum.		
1	29	—	—	⊥	—	—	—	—	±	+	Highly pathogenic.	Shiga.
2	6	—	—	⊥	—	—	—	—	±	—	Similar to above, but relatively inagglutinable.	
3	9	—	—	⊥	⊥	—	—	—	+ to ++	—	Pathogenic Hiss Y type.	Flexner.
4	23	—	—	⊥	⊥	⊥	—	—	+ to ++	—	Pathogenic Flexner type.	
5	8	—	—	⊥	⊥	—	—	—	+	—	Inagglutinable variety of Type 3?	
6	10	—	—	⊥	⊥	⊥	—	—	+ to ++	—	Ditto, Type 4?	
7	3	—	⊥	⊥	⊥	⊥	—	—	+	—	Pathogenic Ohno Type M.	
8	8	—	—	⊥	—	—	—	—	+++	—	Slightly pathogenic.	Morgan.
9	2	—	—	A.sl.g	—	—	—	—	+++	—	,, ,,	
10	2	+	—	⊥	—	—	—	—	+++	—	,, ,,	
11	—	+	—	A.G.	—	—	—	—	+++	—	Morgan No. 1.	

The sign ⊥ = Acid only. A.sl.g. = Acid and slight gas formation.
"Pathogenic" = Lethal to rabbits on intravenous or intraperitoneal injection of living organisms with lesions of the intestine.

Class I.—Shiga group.—The sugar reactions proved to be stable. There is some tendency to vary in the indol reaction, which is never marked and often absent. All but three of the Type 1 strain agglutinated rapidly and completely with the Shiga serum; these three agglutinated in 24 hours.

The Type 2 strains did not become agglutinable on subculture. Strain 99 was agglutinated by 1/50 of the patients' serum on fifteenth day of disease. Strain 98 was not so agglutinated; these latter strains were not agglutinated by the therapeutic serum in a higher dilution than 1/20.

Class II.—Flexner group.—Types 3 and 4 differ only in their action on maltose. They were agglutinated practically to the same titre by the Y serum. According to Hiss, the Y bacillus does not ferment maltose, while the true Flexner type does. Moreover, the production of indol is commonly stated to be greater in the Flexner species. Morgan, however, describes the Y bacillus as a maltose fermenter.

We have found, in common with several other observers, that the fermentation of maltose by organisms agglutinating

Flexner Y serum is variable. It is sometimes possible to select non-maltose fermenting and late maltose fermenters from different colonies of the same strain. The indol reaction is given by all strains to a variable extent, but usually more definitely than by Class I. strain. Moreover, we have found a few strains, such as No. 93, Goodenough, which have a distinct action on saccharose after prolonged incubation. The same remarks as regards maltose also apply to types 5 and 6.

The organisms in these latter types may be divided into two groups: those which become more or less agglutinable to the Y serum after repeated subculture *in vitro*, and those which remain inagglutinable. On the whole, the latter are more often found in acute cases than the former.

The case of a dysentery carrier, 2/AM. O'B., attached to Flying Corps, acting as mess cook, deserves to be recorded in detail. Early in March, 1917, a small outbreak of mild bacillary dysentery occurred in a certain camp near Alexandria; the above-mentioned individual fell under suspicion as a possible carrier of the infection. On March 9th, 1917, a specimen of fæces was forwarded to the Military Laboratory, Alexandria, and reported on as follows:—"Dysentery bacilli (atypical) isolated, Lamblia cysts present." He was then admitted to this hospital. He complained of no symptoms, seldom suffered from diarrhœa; a little mucus was occasionally seen, but more often the fæces were apparently normal.

B. dysenteriæ Type 5 was isolated on 20/3/17, 5/5/17, 10/5/17.

No dysentery bacilli isolated 25/4/17. On 12/5/17 he received 100 c.c. antidysenteric serum intravenously. *B. dysenteriæ* Type 5 was again isolated 27/5/17, 30/5/17, and 5/6/17. Provisionally positive colonies were nearly always numerous on the plate. Negative again 18/6/17.

Strain No. 72 (A.) and Strain 73 (C.) isolated 20/3/17 from two cases of mild bacillary dysentery from the same camp were precisely similar in their character to O'B.'s strains. On 4/6/17 O'B.'s serum gave a good agglutination in a dilution of 1 in 400 against one of his strains. Strains No. 72 and 73 were agglutinated to 1 in 200 and 1 in 400 respectively. *B. dysenteriæ* Flexner was feebly agglutinated 1/50 dilution.

The effect of Y serum on No. 88 (O'B.) was of particular interest. Cultures from four colonies were tested, one was agglutinated up to half titre of the serum, three others to 1 in 10 only. The colonies therefore vary considerably in their agglutinability to the specific serum, the average being low.

On the other hand, Strain 101 (O'B.), though otherwise identical with No. 88, was scarcely agglutinated at all by the Y serum, but was agglutinated to 1/100 by Lister therapeutic serum. Strain No. 101 was injected intravenously into the ear vein of a rabbit. Dose 1/8th agar slope culture in saline. The rabbit died during the eighteenth hour. The intestines were full of slightly blood-stained mucus and intensely congested. The organism was recovered without difficulty from the mucus contents of the intestine and found to be inagglutinable to Y serum.

In addition to being a persistent carrier of dysentery bacilli and a temporary carrier of *Lamblia intestinalis*, the man was also infected with the cysts of *E. histolytica*, which were found on 28/3/17 and 26/3/17. He was treated with 36 gr. of emetine bismuth iodide and subsequently gave six negatives to cysts of *E. histolytica*, the last being on 17/6/17.

The following is a typical example of a microscopic report on a stool while carrying dysentery bacilli only.

17/4/17.—Formed stool; a few specks of mucus on the surface. No cysts. Degenerated epithelial cells present.

The case of O'B. is a notable addition to the records of persistent carriers of dysentery bacilli.

The association between relative inagglutinability of the strains isolated and the clinical mildness of the case is of considerable interest. One of us met with a similar phenomenon during an outbreak of Asiatic cholera at Colombo. At one stage of the epidemic the cases became milder with a lower case mortality. The vibrios became morphologically less typical and less agglutinable with the specific serum used. During a brief recrudescence the organisms again became typical and the case mortality again rose. The Lister Institute therapeutic serum usually agglutinates the types 5 and 6, but in much lower dilution than types 4 and 5.

Similar organisms to type 7 have been isolated by Ohno in Japan and by Bahr in Fiji. The acidity was in each case distinct by the third day, and in the case of Strain No. 75 (Partington) in 24 hours. We understand that this type has also been isolated by Captain Mackie in Egypt.

Strain No. 75 was agglutinated by the patient's serum to 1/100, and also by the Lister Institute polyvalent serum in a dilution of 1/50.

The mannite-fermenting group of dysentery bacilli are to be regarded as somewhat variable members of a closely related species group. By employing a greater variety of carbohydrates and incubating for longer periods and by means of saturation and bacteriolytic tests it would doubtless be possible to separate our strains into further types. Ohno has described 15 types of dysentery bacilli on the basis of the fermentation reactions in lactose, saccharose, mannite, maltose, and dextrine, nine of which belong to the mannite-fermenting group. The work of Hiss, Morgan, Ohno, and others showed that there is a close relation between the fermentation reactions and the receptor mechanisms of these bacteria. It is doubtful, however, to what extent some of the minor differences, such as the late fermentation of maltose and saccharose, are sufficiently stable to be considered specific. Evidence of the instability of some of the fermentation reactions of this group is accumulating. The most constant reactions are those which appear earliest.

Lentz has pointed out that two factors are involved in the reaction produced by dysentery bacilli in broth containing carbohydrates, the acid formation from the splitting of carbohydrates and the alkali formation from the splitting of proteid, and the results are influenced by the constitution of the media used in these tests. We think that the distinction between Hiss Y bacillus and the ordinary Flexner type is largely artificial. It would have been interesting to test some of these strains with the serum of animals immunised to the El Tor bacillus of Willmore. We think it probable that on the basis of the early sugar reactions and cross immunisation experiments our mannite-fermenting strains could be split up into two or three fairly distinct species.

Class III.—Morgan group.—Strains similar to types 8, 9, 10 have been isolated by other bacteriologists in the same endemic area.

The amount of gas formed by different cultures of type 9 is variable; this type is probably closely related to type 8. They differ from the typical Morgan No. 1 bacillus in being non-motile and having apparently a greater pathogenicity to rabbits and guinea-pigs. All the strains in this group gave a marked indol reaction.

Typical Morgan No. 1 bacilli have frequently been isolated from dysenteric stools at different stages of the disease, but particularly during convalescence, and also from the stools of enteric convalescents. Tribondeau and Zichet considered Morgan's bacillus to be an important etiological factor in the dysentery outbreak on the Gallipoli Peninsula. On two occasions we have found the typical organism present in such large numbers in a blood and mucus stool as to suggest that it was the original infecting organism. It seems probable, however, that the closely allied organisms already mentioned play a more important part in the etiology of dysentery. Most of the organisms belonging to the Morgan group were isolated in September and October, 1916.

We look forward to the publication of the researches now in progress in another laboratory in Alexandria on the pathogenicity of the organisms in this group.

Anomalous Strains.

Strain No. 60 (P.), isolated 28/12/16 from a blood and mucus stool from an acute case, was anomalous in not conforming to any of the tabulated types. There were numerous colonies of this organism on the plate. Unfortunately, the culture was found to be dead on subculture three weeks after its first isolation. The following are the characters of the first subculture: non-motile bacillus, lactose acid only, glucose acid only, mannite no change, maltose acid only, saccharose no change, dulcite no change after three days at 37° C., indol reaction slightly positive. No agglutination in 1/10 titre of either Shiga or Y serum.

Table II. shows the kind of stools from which the various organisms were isolated:—

TABLE II.

Type No.	Acute stool.	Sub-acute.	Fæcal	Total No.	Type No.	Acute stool.	Sub-acute.	Fæcal	Total No.
1	28	1	—	29	5 & 6 ...	8	6	4	18
2	1	5	—	6	7	1	2	—	3
3 & 4 ...	23	6	3	32	8, 9, & 10	7	4	1	12

The stools are classified as before. It will be noted that the agglutinating Shiga type is more constantly associated with the acute type of blood and mucus stool containing cellular exudate than the corresponding Flexner type. The single strain found in a subacute type of stool was one of the three which did not agglutinate well.

As suggested by these figures, the non-agglutinating Flexner and Shiga types are those most commonly isolated from mild cases of bacillary dysentery. This accords with the experience of the physicians in charge of the cases. The probability is that the actual proportion of non-agglutinating atypicals is greater than would appear from these figures, since the chances of isolating them from the subacute and fæcal type of stool are less. Captain Fisher states that

on the whole good results were obtained with the polyvalent serum in the treatment of cases in which only atypical strains were isolated. A large proportion of the types 2, 5, and 6 infections did not require serum treatment. Nevertheless, in view of the low agglutinability of some of the atypical strains recovered from acute cases to the therapeutic serum it would seem that the serum is not sufficiently polyvalent.

Nearly all the cases of bacillary dysentery came from the same endemic area—namely, camps in the vicinity of the hospital. There is some evidence of a seasonal variation in the different types of bacilli isolated. The small outbreak in March, 1917, already mentioned, bred true to type—i.e., all the cases were infected with the same type of organism, presumably through the agency of a carrier. Nevertheless, as a general rule, typical Shigas, typical Flexners, and various atypical organisms could be isolated from cases from the same camp at all seasons, though in different proportions. This is probably to be accounted for by the simultaneous spread of the different types through the agency of flies feeding on a variety of fæcal matter deposited by natives in the neighbourhood of the camp.

In Japan, in the Philippines, in the Fiji Islands, and other localities a similar diversity of species has been described. On the other hand, most local epidemics in Germany and in English asylums are attributed to some particular species of dysentery bacillus, and stress is laid on human carriers as a means of spreading the virus.

V.—AMŒBIC DYSENTERY.

By Captain THOMSON.

Acute Amœbic Dysentery.

During the year 1916 a total of 666 specimens of fæces from separate cases contained blood or mucus, or both. Of these 97 cases were found to contain free living *E. histolytica* diagnosed chiefly by the presence of ingested red blood cells.

Out of the total acute cases of dysentery examined in the laboratory, 14·5 per cent. proved to be amœbic. Of these, 19 were diagnosed bacteriologically and microscopically to be mixed infections—that is, both amœbic and bacillary. Nine more cases were diagnosed as a double infection on clinical grounds, making a total of 28 mixed cases. I think it very probable that several cases of mixed infection were missed during the acute attacks of bacillary dysentery, especially when the amœbic infection was slight.

Only three deaths occurred in which an amœbic infection was active. One of these had the complication of enteric fever; another had an acute bacillary infection, and one died from a perforated amœbic ulcer about 10 inches above the anus. Of these deaths, therefore, only one could be attributed to the action of the amœbæ alone—that is, the death-rate in pure amœbic cases in this hospital during the year was approximately 1 per cent. amongst amœbic cases and only 0·15 per cent. of the total cases of dysentery. No deaths occurred from amœbic abscess of the liver, and only one case of amœbic abscess was treated surgically.

This low death-rate in amœbic dysentery can be attributed to two things: (1) That amœbic dysentery is often not very virulent; (2) the specific treatment we possess in emetine and ipecacuanha.

During the Gallipoli campaign, before emetine was sent to the base and before the drug was administered early, most extensive lesions of the large intestines were often seen by us in the post-mortem room, which proved in sections of the gut to be amœbic. These were often complicated by secondary infections, causing destruction of the whole mucosa right down to the muscular layer and in many cases right down to the peritoneum, and perforations were not uncommon. The observations made during the original outbreak of dysentery on the Gallipoli Peninsula prove conclusively that amœbic dysentery was an important factor in causing many fatal cases, and the necessity of prompt treatment with emetine in all suspected cases was advocated and carried out. The death-rate fell in a remarkable manner as soon as emetine was introduced into the base hospitals and hospital ships.

The explanation of the various results obtained by treatment is to be found by the study of the pathology of the intestine during dysentery. In mixed cases of dysentery—that is, both amœbic and bacillary—we find that the bacillary condition causes an acute congestion of the whole capillary system of the large intestine, extensive submucous hæmorrhages occur, and thus the circulation to the gut is cut off. In these cases it is quite impossible for any emetine injected hypodermically to reach the amœbæ buried in the submucosa. It is first necessary to cure the bacillary condition and to restore the circulation in the intestinal mucosa. Again, in more chronic cases of active amœbic dysentery—that is, in cases persistent for some time with the passage of free entamœbæ in the stools, we often have a considerable amount of fibrous tissue formation, and, consequently, we have the amœbæ shut off from the circulation. In these cases it may be impossible or difficult to reach the amœbæ either by circulation or by the mouth. We know these pathological changes in the intestine exist in varying degrees depending upon the acuteness or chronicity of the condition.

Certainly the best results in treating acute amœbic dysentery are obtained at the first onset of the acute attack. Administer emetine hypodermically and orally and so attack the amœbæ before they are shut off either from the circulation or the lumen of the gut by fibrous tissue formation or damage to the capillary blood-supply.

If the first course of treatment fails we must, after an interval, recommence treatment, and in our experience very few cases will fail to respond to the action of emetine when given hypodermically and by the mouth.

Chronic Amœbic Dysentery Diagnosed by the Presence of the Cysts of Entamœba histolytica.

Out of a total of 1785 cases examined the pathogenic cysts of *E. histolytica* were found by me in 2·4 per cent. Wenyon and O'Connor (1916), in Alexandria, found cysts in 3·2 per cent. of hospital cases examined, and in 5·3 per cent. of healthy British troops in Egypt.

These observers also found that 13·7 per cent. of native prisoners in Hadra were carriers of amœbic dysentery. The cysts of *E. histolytica* are characterised by the presence of four nuclei, and, as shown by James, Penfold, Woodcock, Wenyon and O'Connor (1917), and Dobell and Jepps (1917), they varied much in size.

Dobell and Jepps give the diameter as varying between 7μ and 20μ. The paper by Dobell and Jepps is a most useful contribution to the diagnosis of the three common intestinal entamœbæ in man.

I have found most commonly in my cases here sizes between 10μ and 15μ in diameter. Some of these cases give no history of ever having had acute dysentery, and many never even complained of diarrhœa. All cases had spent several months in Egypt, and several gave distinct histories of dysentery and the passage of blood and mucus. Others came from Salonika, Mesopotamia, India, or had been through the Gallipoli campaign. In the series of 42 cases received here we find that none had been treated with emetine, but several had received injections of serum and been treated as acute bacillary dysentery. It seems to me quite certain that when a patient is a carrier of the cysts of *E. histolytica* there must be some ulcerative process in the gut. Wenyon and O'Connor (1917) are of the same opinion. In the post-mortem room during the last two years I have noticed the presence of amœbic ulcers of the large intestines where no dysentery was suspected, and in many of the cases examined by me where the stool was found apparently normal and where numerous pathogenic cysts were present I have found microscopically Charcot-Leyden crystals, a certain indication of the presence of broken-down blood corpuscles. We have, as it were, in all cases of cyst carriers of the pathogenic entamœbæ an occult condition of ulceration which does not make itself always obvious microscopically.

A cyst carrier may continue healthy and well for years, but nevertheless he is a danger to himself and the community, especially in badly sanitated areas.

FRACTURES OF THE FEMUR:

A PRACTICAL NOTE ON THE CALLIPER AS AN INSTRUMENT OF EXTENSION.

BY P. L. WATKIN WILLIAMS, D.S.O., F.R.C.S. EDIN.,
TEMPORARY CAPTAIN, R.A.M.C.

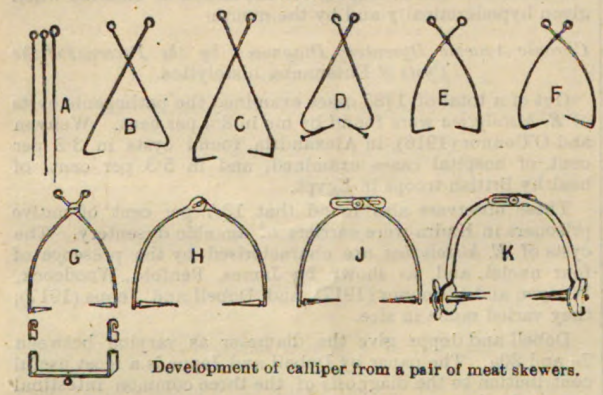
THE treatment of fractures of the femur has received considerable attention of late. A large number of mechanical appliances have been devised, the majority of which may be swept aside as ingenious toys, too elaborate and expensive for everyday use. Moreover, the best results can be obtained with very simple apparatus, properly applied.

Extension and Immobilisation.

Extension and immobilisation are fixed principles that nobody disputes, but there is considerable difference of opinion as to how extension is to be made and maintained, and how much immobilisation includes. All methods of extension come under two heads: the so-called "fixed" extension, and extension by counter-weight.

The Thomas splint is used in large numbers both in France and at home, but in a variety of ways, and many of them are certainly not acting on the Thomas principle—which, of course, is that the ring is pressed against the ischial tuberosity and the leg tied to the other end of the splint as forcibly as can be done, this being the true fixed extension.

FIG. I.



Development of calliper from a pair of meat skewers.

In many cases shown as examples of this method the bed is raised at the foot, the splint tied to a post at end of bed, and the ring is found an inch or two away from the pelvis; extension is therefore really being made by the body weight pulling away from the fixed limb, practically the Hodgen principle. The objection to this method is that the patient can ease the pull, if it is uncomfortable, by working himself along the bed.

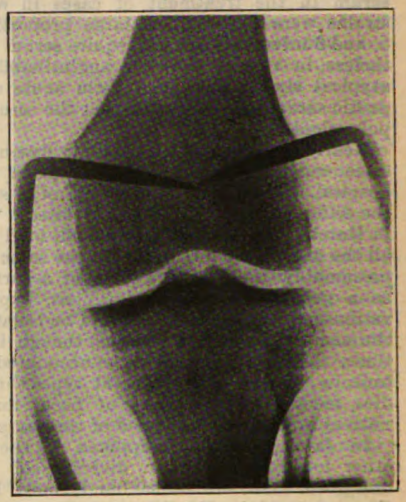
Another way of using the Thomas splint is to suspend the limb in it, using it merely as a cradle and fixing the limb extension to an independent post, or making extension by pulley and counter-weight, the bed foot being raised in the usual way. An objection to this method is that the whole limb is used for extension purposes, and therefore the knee is kept continuously in one position.

This brings up the question as to how much immobilisation includes. The older text-books lay it down as a rule that when possible the joints above and below the fracture should be included in the fixation. This practice is still being largely adhered to and has the disadvantage that convalescence is prolonged by the time necessary to restore mobility to the knee-joint.

I described in THE LANCET of Feb. 23rd, 1918, a splint which permits of passive movement of the knee-joint while maintaining extension of the thigh, practically a Hodgen with a second frame for the leg, hinged to the thigh frame at the knee level. The same leg-piece can be hinged into a Thomas if preferred, and this method has given very satisfactory results.

Where possible, then, the mechanical treatment of a fractured thigh should include fixation of the thigh with freedom of the knee and leg. This leads to a consideration of the best way of obtaining a hold of the thigh for purposes of fixation and extension. Essentially there are but two methods: in the one the pull is taken from the limb surface by some adhesive applied to the skin; in the other a direct hold is obtained on the bone by some instrument.

FIG. II.



Unnecessary penetration of points of calliper before modification.

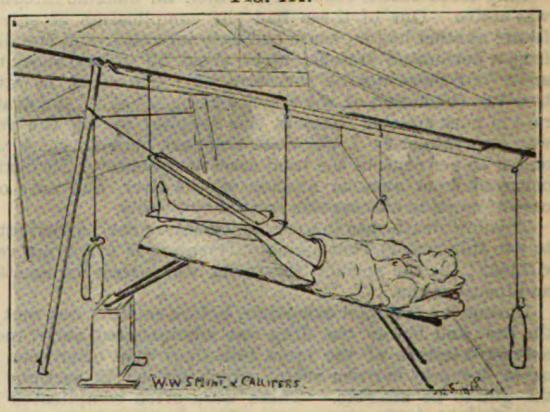
There can be no question that the latter is the more efficient, and comparing the number of cases I have seen of skin infection, abscess, deep sloughing, and occasionally gangrene following the use of strapping and glue, with the number of cases with sepsis following the use of instrumental extension, I have no hesitation at all in saying that the instrument is infinitely safer—and if further argument is needed patients who have been subjected to both invariably decide against the adhesives.

Account of Use of Calliper.

One of the most recent instruments is that devised by Major Besley, of the U.S. Army, and called by him the "ice-tongs" or calliper. For simplicity of application and minimum injury to bone it seems superior to other instruments, while giving absolute precision of control over the fracture. I have used this instrument for some considerable time, and have introduced some modifications which have met with Major Besley's approval, and therefore I hope they may be worth describing.

The development of the Besley calliper from a pair of meat skewers to the instrument known by that name is shown in the top row of Fig. I. The points are inserted a short distance into the condyles of the femur and the pull taken from the rings at the other extremity. It is obvious that the heavier the pull the more the points would be driven into the bone, not infrequently to the extent shown in Fig. II.—a quite unnecessary injury to the bone; and therefore the first modification was the substitution of a screw-joint for the simple rivet (Fig. I. G).

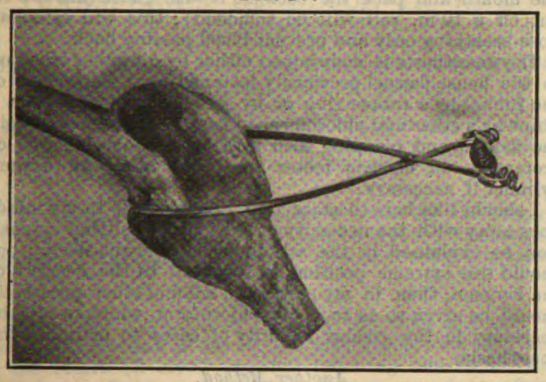
FIG. III.



Splint and callipers in use, with extension on Hodgen principle.

Both the calliper and extension cord attached are in the way if free movement of the knee-joint is desired; the pull was therefore shifted to the pins and taken by a rigid metal frame long enough to extend beyond the foot, which permits of the foot passing up inside it (Fig. III.). The short arms with ring ends are therefore unnecessary (Fig. I. B).

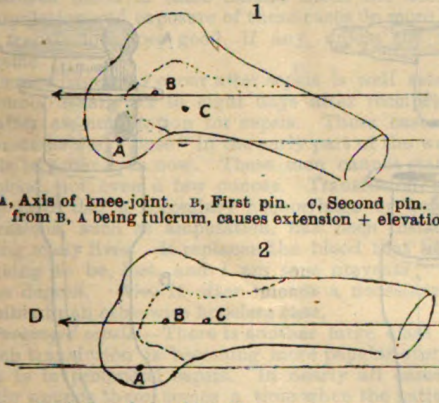
FIG. IV.



Knee-joint distended with paraffin to show available surface for callipers. (Specimen and photograph by Major Besley.)

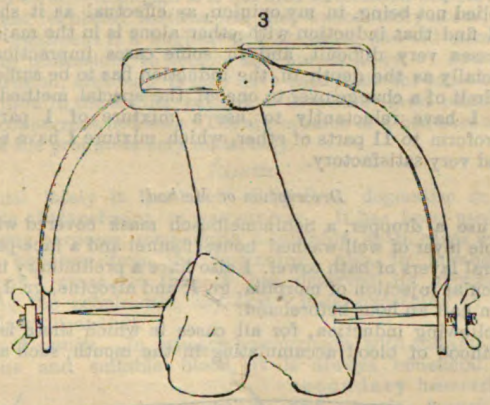
The body of the calliper can then lie on either the thigh or leg, but if moved from one position to the other causes pain, which is due to the fact that the two pins are hardly ever in one straight line, as shown in the Fig. I. G; at any other position of width they are, of course, at an angle as in the top row figures, and therefore, when moved on their axis, cause pressure on the bone. To obviate this the hinge-joint was expanded laterally (Fig. I. J), so that at any width the pins are in one line.

FIG. V.



A, Axis of knee-joint. B, First pin. C, Second pin. Pull from B, A being fulcrum, causes extension + elevation.

B and C being clamped together A ceases to be a fulcrum. Pull from C through B = extension only.



By elevation of pulling rod in direction D, B becomes fulcrum and hyper-elevation is corrected.

Fig. III. shows this instrument in position, with the metal extension frame and the modified Hodgen splint, which differs from that shown in the previous article in THE LANCET to the extent that the thigh frame is lengthened to correspond to the other, and, for the same reason, to allow the foot to pass through to full extension of the knee. As shown in the figure, a counter-weight is arranged to balance the weight of the leg in such a position that the patient can control it and so produce passive movement of the knee at will.

This arrangement is comfortable for the patient and permits him a reasonable amount of movement without disturbance of the fracture, gives ready access to wounds, and can be placed in any degree of abduction required. I have heard of callipers remaining *in situ* for seven and eight weeks, but in my experience three to five weeks is sufficient in the average case. After that time, when some active movement is not only permissible but desirable, a simple weight extension attached to foot or leg, with no splint at all, is the best arrangement, the patient being taught to put the different muscles into action against the pull of the weight.

Fractures of Lower Third of Femur.

There is one other point of interest in the use of the calliper, which was not apparent when it was originally devised, and that is the treatment of lower third fractures. The method of application is simplicity itself, the only point of importance being avoidance of the synovial membrane.

Fig. IV. is a photograph of a specimen prepared by Major Besley to show the area of bone available and its relation to the joint; and Fig. V. shows the relation of the available area to the axis of the joint, which is such that no matter what spot is chosen for the insertion of the calliper point a lever action is produced, with the knee axis as fulcrum, the result being that with a short lower fragment a certain and unavoidable amount of elevation is produced, apart from the extension. As in nearly every case the lower fragment is depressed, this is beneficial, but the action will continue indefinitely and produce hyper-elevation unless checked by the reduction of the amount of pull or alteration in its direction. Another alternative is to arrange a pull on the leg by strapping or foot-piece, and lessen the pull on the thigh, balancing the one against the other. This, of course, at once interferes with the freedom of the knee. The diagrammatic outlines of skiagrams in Fig. VI. are a sample of this frequent over-correction.

In order to obviate the necessity for readjustment I have devised a calliper with two points on each side instead of one (Fig. I. K). Both, of course, are inserted into the bone, but at first the pull is taken from one only, that nearest the knee; the ordinary lever action operates and the fragment is elevated. When alignment is judged correct the screw nut is tightened on each side, and then the pull is taken from both pins, the lever action is arrested, or—more correctly—altered, as the first pin becomes the fulcrum, and further pull results in maintaining extension only. Fig. V. illustrates this perhaps more clearly than words can describe it. This last pattern has not been given sufficient trial to warrant its being offered as more than a suggestion.

The single-point sliding-joint calliper with metal extension frame is made by Messrs. Down Bros. and has been accepted by the War Office, and made for me, so presumably it can be obtained in the usual way by others who may wish to use it. I am greatly indebted to Major Munro, R.E., and to Captain Hill, R.E., for their skill and interest in the making of these appliances and other surgical requisites, and particularly so considering the limited apparatus and labour at their disposal in France. My acknowledgments and thanks are due to Major Besley for allowing me to sketch his instruments and to publish this description of them and for accepting so cordially the small modifications I have suggested.

ETHER ANÆSTHESIA FOR FACE AND JAW SURGERY.

BY J. C. CLAYTON, M.R.C.S., L.R.C.P. LOND.,

CAPTAIN (T.C.); ANÆSTHETIST, QUEEN'S HOSPITAL, SIDCUP, AND ROYAL EAR HOSPITAL, LONDON.

AFTER six months' experience at the Queen's Hospital for Face and Jaw Injuries, during which time I have administered 400 anæsthetics for minor and preparatory operations and 100 for actual plastic operations, I should like to supplement a most able article published in THE LANCET by my colleague, Lieutenant R. Wade.[1]

In that article Lieutenant Wade dealt most fully with various techniques for various operations, including intratracheal, intubation, colonic ether, and a special sitting-up position; but whereas he is satisfied with the free use of chloroform in combination with ether, I personally feel convinced that, just as in general surgery, chloroform should as far as possible be eliminated in favour of ether.

Consequently, I have been at pains to work out different methods of sustaining an ether anæsthesia to meet the various operations required. Owing to the ether at present supplied not being, in my opinion, as effectual as it should be, I find that induction with ether alone is in the majority of cases very difficult, and in some cases impracticable, especially as the depth of the induction has to be sufficient to admit of a change over to one of the special methods, so that I have reluctantly to use a mixture of 1 part of chloroform to 11 parts of ether, which mixture I have so far found very satisfactory.

Description of Method.

I use a dropper, a Schimmelbusch mask covered with a double layer of well-washed house flannel and a face-pad of several layers of bath towel. I also have a preliminary intramuscular injection of morphia, gr. ¼, and atropine, gr. 1/100, given half an hour beforehand.

Following induction, for all cases in which there is any likelihood of blood accumulating in the mouth, such as lip

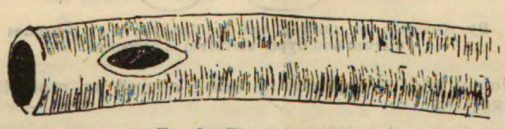

FIG. 1.—The nasal tube.

plastics, epithelial inlays inside the mouth, antral and submental drainage, and extensive extractions of teeth, I use a single nasal tube, the largest which I can pass down one nostril, having a small hole cut at the side close to the tip, and the edges of the tip trimmed. (Fig. 1.) This tube is connected to a tube of larger calibre, a most important point, this larger tube being further connected with an enamelled funnel of about 4 in. in

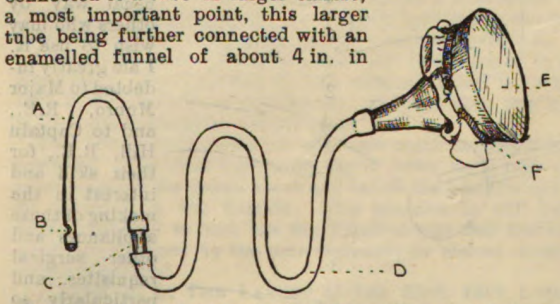

FIG. 2.—A, Nasal tube; size No. 14 to 16. B, Hole at end of nasal tube; C, Large metal connector. D, Tube; size No. 20. E, 4 in. funnel covered with house-flannel. F, Rubber band.

diameter, and it is again important that the diameter of the spout of the funnel is no smaller than that of the tube attached. (Fig. 2.)

By holding the funnel to the ear and adjusting the nasal tube one finds the point, which is somewhere just above the epiglottis, at which the breathing is comfortable. Then open the mouth and pack the back of it with gauze (about 2 ft. cut off a 10 in. roll will be sufficient); this will establish nose-breathing only and prevent blood passing back.

The anæsthesia is maintained either by dropping ether on to the house flannel previously fastened over the mouth of the funnel by a rubber ring or by passing the tube from a Shipway's ether and chloroform apparatus through a hole in the flannel and pumping with a Fletcher's foot bellows, or preferably an electric motor pump, or using an oxygen cylinder if necessary.

I should like here to state that this method, to my mind, does away with the necessity of the extreme sitting-up position, as explained in the article by Lieutenant Wade; but should this extreme position be essential to the comfort of the surgeon, then, in my opinion, a colonic ether anæsthetic should be given so as to avoid chloroform, which would be necessary in the greater majority of cases to maintain the anæsthesia.

Another Method.

A method in such cases as plastics on the nose, eye, or cheek, or in fact where there is no likelihood of blood entering the mouth—and among these cases may also be included both septal and antral cases where a post-nasal plug is used—is one where a Hewitt's airway tube as

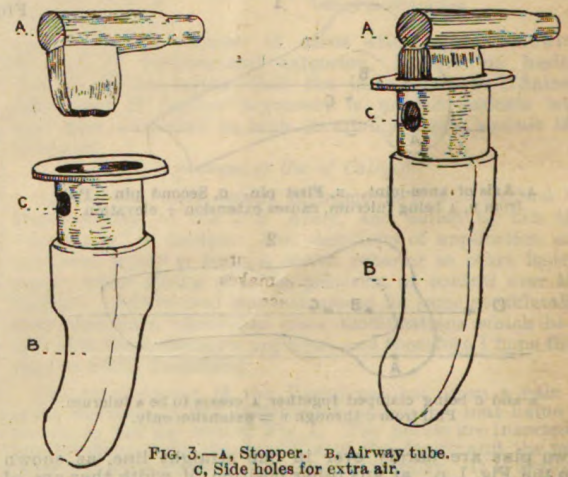

FIG. 3.—A, Stopper. B, Airway tube. C, Side holes for extra air.

modified by Phillips is used. I use this tube because it is at present the only one which I can get supplied, but not necessarily from preference. This tube has a hole through each side of the metal portion, and I have had a hollow stopper made to fit the mouth of the airway tube in connexion with a horizontal tube, actually an empty rifle cartridge case, the free end of the stopper being graduated so as to leave the two side-holes patent to act as respiratory vents, and still keep a large ether way. (Fig. 3.)

The horizontal tube can be turned either to the right or left as required, and is attached by tubing either directly to the Shipway's apparatus or to the enamelled funnel as described above. I frequently find that when attached directly with the Shipway's apparatus an automatic inhalation of ether is set up sufficient to keep the patient comfortably anæsthetised without any pumping.

I do not wish to suggest that these methods take the place of intratracheal ether, but will be found useful substitutes, especially when the injury prevents a good opening of the jaws.

With regard to intratracheal, intubation, and colonic ether anæsthesia, I cannot say more than has been said in Lieutenant Wade's article, except that in colonic ether we are finding that the results are just as good without using hyoscine in the hypodermic injection.

[1] THE LANCET, June 8th, 1918, p. 794.

LITERARY INTELLIGENCE.—New editions of the following books are announced by Messrs. J. and A. Churchill: "Surgery in War," by Lieutenant-Colonel A. J. Hull, R.A.M.C., second edition; "A Text-book of Pharmacology and Therapeutics," by Professor A. R. Cushny, F.R.S., seventh edition; "Diseases of the Eye," by J. Herbert Parsons, F.R.C.S., third edition.

TRANSFUSION OF BLOOD IN WAR SURGERY:

SOME INDICATIONS AND RESULTS, AND DESCRIPTION OF NEW MODIFIED DIRECT METHOD.

BY S. R. HARRISON, M.R.C.S. ENG., L.R.C.P. LOND.,
MAJOR, C.A.M.C.; OFFICER IN CHARGE, SURGERY, NO. — CANADIAN GENERAL HOSPITAL, SHORNCLIFFE.

THE indications for transfusion of blood in war surgery are: (1) anæmia, caused by (*a*) loss of blood, (*b*) prolonged sepsis; (2) retarded healing of wounds, including compound fractures.

Anæmia.

Severe loss of blood may occur at the time a soldier is wounded or within a day or two afterwards, and then due to the return of blood pressure removing blood clot, &c. Transfusion of these primary hæmorrhage cases is beneficial immediately and permanently, so long as the blood of the donor is suitable and the "wound" shock not too great. Some transfusion enthusiasts claim a great deal for it in surgical shock; still, when we consider what we know of the pathology of shock, we must not expect too much of transfused blood in these cases. Often the accompanying manipulation and exposure of these cases do more harm than the transfusion does good, if any, unless the anæmia is extreme.

Hæmorrhage may occur after sepsis is well established in a wound, usually six to eight days after receipt of wound, or after an amputation for sepsis. These cases were very common at the "Base" in the early part of the war, and are liable to occur even now. These men cannot stand the loss of blood, not even a few ounces. Transfusion, either after they have had a secondary hæmorrhage or before severe operations, such as amputation, has been instrumental in saving many lives. It replaces the blood that has been, or is going to be, lost, and I am sure prevents "shock" in some degree. Also it often makes a necessary operation possible in an otherwise hopeless case.

Prolonged sepsis.—There is another large class of case in which transfusion is becoming more popular every day, and that is in prolonged sepsis. In nearly all cases of severe septic wounds there comes a time when the patient's resistance becomes exhausted. His wounds have an "indolent" appearance, and healing is slow or absent; he has loss of appetite, and has no "kick" left in him. These cases are always profoundly anæmic. The coagulability of the blood is diminished, there is œdema of the back and legs, and often pus in the urine.

There are many types of this picture I have tried to describe, from the case of a slowly healing stump to the case of pyæmia. From my own observation over many months I find that they are all improved by a suitable transfusion, the severe cases temporarily, the mild cases permanently. Until lately transfusion has only been used in almost hopeless cases, or rather not employed until they were almost hopeless. I believe that the injected blood is directly stimulating to the tissues, so that I advise it to be used early in the case, before the body has lost its power of reaction.

There are now being recorded many cases of "prolonged sepsis" which clinically appear to be septicæmic, and which become well either with or without transfusion. My own observation goes to show that all these cases improve by transfusion so long as the donor's blood is properly examined in conjunction with that of the recipient. It is therefore probable that the donor's blood contains antibodies which may affect the life of the micro-organism probably present in the recipient's blood. It is conceivable that this process might be carried out more effectively by a preliminary vaccination of the donor with autogenous vaccine prepared from the recipient, if the organism can be recovered and the septicæmic recipient does not succumb in the interval necessary for such antibodies to be produced in the donor.

In primary hæmorrhage the most satisfactory amount of blood to use appears to be from 750 to 800 c.cm. given at one transfusion. In septic cases smaller amounts are indicated, 300 to 500 c.cm. repeated in 7 to 10 days, using a fresh donor each time. Donors under the age of 25 seem to stand the withdrawal of blood very well, and after a few hours feel quite fit again.

Retarded Healing of Wounds.

"Indolent" wounds.—These so-called "indolent" wounds have usually large raw surfaces, with no, or very anæmic, granulations upon them, and they show no sign of healing, the skin edges often being blue and lustreless. In the early part of the case there has been much discharge, and there has of necessity been a heavy drain upon the patient's fluid blood. There is no reaction in the wound. There may be no increase of temperature, but as a rule the pulse-rate is still rather high. Stimulating dressings do no good; some, such as saline, often cause troublesome hæmorrhagic oozing, which has a deleterious effect upon the patient. Non-healing stumps may be mentioned as one of the most common types in this category. Repeated blood transfusion of, say, 400 c.cm. at ten-day intervals, is most beneficial.

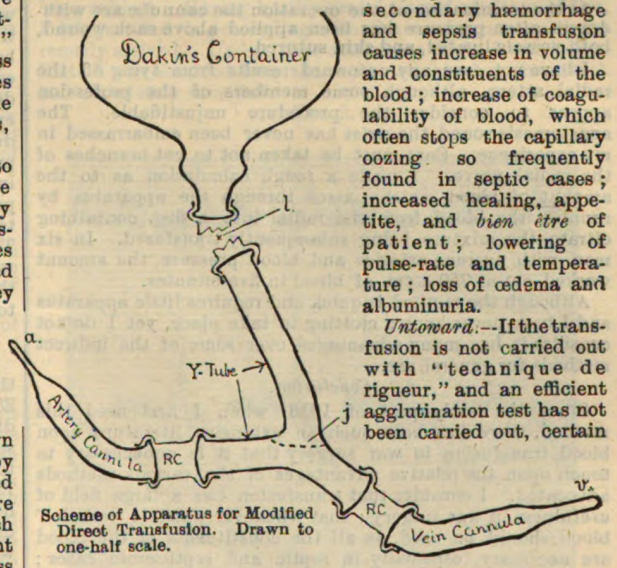
Compound fractures.—The same remarks as have been made about "indolent" wounds are applicable to septic compound fractures, especially those of the femur. There is no doubt that in long-standing cases, where the suppurative process continues in a "watery" manner and there is persistent non-union and no attempt on the part of the patient to react to the infection or throw out new bone, repeated small transfusions increase the production of osteoblasts and alter the appearance of fragments under the X ray which previously may have been considered "dead."

Bed-sores.—Although it is not nice to mention bed-sores in the best regulated institutions, they undoubtedly occur, and their treatment is a bugbear to both young and old members of the profession, to doctors and nurses alike. I find that transfusion, although it may have been done for some other condition in the soldier patient, is invariably most beneficial to a concurrent bed-sore. The appearance of a bed-sore often alters the prognosis very materially.

Results.

Until lately it has been difficult to dogmatise on the results of transfusion in war surgery. It has been used for so many purposes, some quite unsuitable, as in cases which were hopeless from the beginning; also, in numberless "shock" cases, so that it has deserved its reputation among the people who say that "it is something to do" and leave it at that.

Good results.—In primary hæmorrhage, with suitable conditions and suitable blood, it is always beneficial. In secondary hæmorrhage and sepsis transfusion causes increase in volume and constituents of the blood; increase of coagulability of blood, which often stops the capillary oozing so frequently found in septic cases; increased healing, appetite, and *bien être* of patient; lowering of pulse-rate and temperature; loss of œdema and albuminuria.



Scheme of Apparatus for Modified Direct Transfusion. Drawn to one-half scale.

Untoward.—If the transfusion is not carried out with "technique de rigueur," and an efficient agglutination test has not been carried out, certain alarming or even fatal results may take place. Immediate: hæmolysis, agglutination, possibly causing sudden death; cyanosis, with feeble pulse, possibly caused by giving too large a volume of blood when the heart muscle is degenerated from sepsis. Later: sweating, rigors, pyrexia, apparently found more frequently after giving citrated blood; hæmaturia.

Modified Direct Method.

The rationale of this method is to convey blood from an artery of the donor to a vein of the recipient and allow the operator to observe the flow, so that he knows immediately if the flow should cease or if any clotting is taking place.

The apparatus is very simply "home made." It consists of a Y-tube (see figure), two limbs of which are shortened, and two glass cannulæ. These cannulæ are connected to the short limbs of the Y-tube by sterilised rubber tubing (R C); the third limb is connected (*l*) with a reservoir of saline 0·8 per cent. or sodium citrate 3·8 per cent. by tubing about 5 feet long, which has a clip on it. All rubber connexions are conveniently tied with silk. The length of the instrument—that is, the distance the blood must flow through the tube, is about 6 inches. The diameters are: of tip of artery cannula (*a*) 1 mm. internal and 2 mm. external; of vein cannula (*v*) 2 mm. internal and 3 mm. external; of Y-tube cannula 6 mm.

The Y-tube and cannulæ are waxed after sterilisation and joined up in position with rubber tubing which has been duly sterilised. The long limb of the Y-tube is now connected to the reservoir of sodium citrate solution and the apparatus is ready for use.

The operation is as follows:—

The donor's left radial artery is usually taken (unless he is left-handed), the distance between artery and the selected vein in recipient is roughly measured off with instrument, and the two arms secured in position with adhesive. Two operators are necessary: one to prepare the artery and one to prepare the vein.

The skin over the proposed wound is sterilised with 1-20 carbolic, which also acts as an anæsthetic. The radial artery 1½ inches above wrist is dissected out through an inch incision, tied off distally with fine silk, a second loop of which is passed under the artery and used later to tie in the cannula. The artery is now opened with a Graefe's knife from above downwards and outwards, leaving a V-shaped tongue. Pressure in the meantime is applied above the wound to prevent loss of blood.

The vein is prepared in the same way. The clip on the tubing leading to the reservoir is now opened, and the apparatus filled with citrate. The artery cannula is now tied into artery and blood allowed to flow until it reaches the tip of vein cannula, when pressure is again applied to artery. The vein cannula is then tied into vein and all pressure taken off artery. The blood can now easily be seen flowing through the Y-tube at the junction of the short and long limbs where the clean solution of citrate comes in contact with the blood (*j* in figure). This can be more easily demonstrated by occasionally opening the clip on the tube to reservoir, which is suspended about 3 feet above the patient, when the clear solution is seen passing quickly into the vein cannula. This is even more pronounced if pressure is applied to the artery.

At the termination of the operation the cannulæ are withdrawn after pressure has been applied above each wound, both vessels ligated, and skin sutured.

I have not seen any untoward results from tying off the radial artery, although some members of the profession appear to consider the procedure unjustifiable. The anastomosis round the wrist has never been embarrassed in my experience. Care must be taken not to cut branches of the radial nerve. I made a rough calculation as to the amount of blood which passes through the apparatus by running the blood from the radial into a dish containing citrate, the mixture being subsequently transfused. In six men, with average arteries and blood pressure, the amount worked out at 750 c.cm. of blood in five minutes.

Although the method is quick and requires little apparatus and I have never known clotting to take place, yet I do not consider it has many advantages over some of the indirect methods for general use.

Conclusion.

Since the early part of 1916, when I first used this method, there has been such an extensive literature upon blood transfusion in war surgery that it is unnecessary to touch upon the relative advantages of the various methods advocated. I consider that transfusion has a large field of usefulness in war surgery; that whenever possible "whole" blood should be used, as all the constituents of the blood are necessary, especially in septic and septicæmic cases; that a preliminary agglutination test should always be carried out, except when the groups of donor and recipient are known; and that the "Dakin container" indirect method is the most simple and efficient method for general use, as the apparatus is easily made or obtainable, the required amount of blood can be given at one filling, and little assistance is required, also whole warm, unadulterated blood, with little chance of infection, is quickly transferred from one patient to another. Of course, the method selected must necessarily vary according to circumstances of location and available apparatus.

ABNORMAL CONDITIONS OF ENAMEL IN CASES OF MALNUTRITION.

BY J. LAWSON DICK, M.D. EDIN., F.R.C.S. ENG.,
ASSISTANT SCHOOL MEDICAL OFFICER, LONDON COUNTY COUNCIL.

APART from caries there are many abnormalities to be found in the enamel of the teeth in cases of malnutrition. If 100 good-class children are compared with 100 poorly-fed, ill-nourished children, even a casual inspection will show that the teeth of the poorly-fed children are much more defective than those of the better-fed ones.

The study of defects in the enamel is a matter of much interest and importance, for there is, as it were, a permanent record in many cases of the state of the child's nutrition at various periods of life. The calcification of the enamel begins about the fifth month of intra-uterine life, and the following diagrams give the rate of progress of calcification at various periods for both the temporary and the permanent sets.

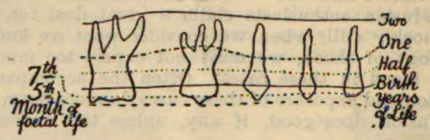

FIG. 1.

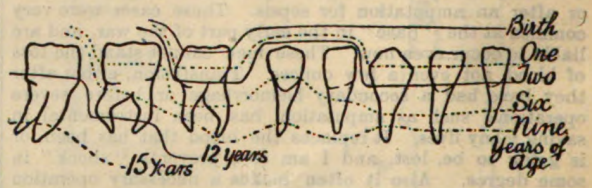

FIG. 2.

It is extremely rare to find the cutting edge of the incisors and canines of the milk teeth with imperfect enamel, and it will be seen that this enamel is laid down or calcified during the last four months of intra-uterine life. On the other hand, it is quite common to find the enamel of the cutting edge of the same teeth of the permanent set markedly defective. This enamel is laid down in the first year of extra-uterine life. In other words, in almost all cases during intra-uterine life the calcification of the enamel proceeds normally, but immediately after birth factors step in which interfere with the proper growth of the enamel, producing defects which are permanent and which are likely to weaken the defences of the teeth and to lead to decay. The agents which determine the tendency to decay are those which affect the soft enamel organ in the earliest history of the tooth and not those which affect the enamel after the tooth has been erupted.

Results of Investigation.

403 children of 11 years of age and over were taken from the ordinary London County Council schools, but of these 281 were children in schools where the nutrition was distinctly below the average. No attempt was made to select children of poor nutrition beyond that they belonged to a poor school and lived under slum conditions in the East-End of London in a poor and overcrowded neighbourhood. As a control 122 children were taken from good-class schools in North London, where the social conditions were fairly good and where the general state of nutrition was good. The following were the figures:—

(A) 403 children. (B) 281 where nutrition was decidedly poor.
(C) 122 children of good nutrition.

	(A)	(B)	(C)
Enamel normal ...	273 cases = 67·5%	... 167 = 60%	... 106 = 87%
,, defective ...	130 ,, = 32·5%	... 114 = 40%	... 16 = 13%

Carious conditions have not been dealt with in these figures. The conditions of the enamel met with in these cases may be summarised as follows:—

1. *Typical hypoplasia.*—As already noted,[1] in these cases the enamel of the teeth is markedly defective, so that the

[1] The Teeth in Rickets, Proceedings Royal Soc. Medicine, 1916, ix., 83-89.

dentine is but thinly and unequally covered. The cutting edges may present sharp points, giving a very characteristic appearance. The defect usually extends from the cutting edge, and may, in severe cases, involve the whole crown. The teeth affected are the central and lateral incisors, the tips of the canines, and the crowns of the first molars of the permanent dentition. Usually the depth of the defect is greater in the enamel of the central incisors than of the lateral incisors, and the enamel as a rule affected is the enamel laid down in the first two years of the child's life. This condition is almost pathognomonic of rickets.

2. *Honeycombed teeth.*—This condition is much the same as the first, except that the deficiency in the enamel leads to the formation of small depressed pits scattered over the surface of the teeth, giving a very characteristic appearance.

3. *Horizontal bands of thickened enamel and transverse grooves in the enamel*, indicating acute illnesses of a more or less prolonged nature. Short acute illnesses seem less likely to produce this condition than prolonged debilitating conditions such as measles, especially when followed by whooping-cough.

4. *Chalky appearance of the enamel*, varying from white patches or transverse bands on the surface of the enamel to a general opacity affecting its whole surface. This is a very well-marked defect, and the contrast which this condition gives with the clear semi-transparency of healthy enamel is one of the chief things that strike the observer in the teeth of poorly nourished children. As will be seen, it is the commonest defect found in malnutrition.

5. *Brown lines of Retzius* or brown staining of the enamel is a common and well-marked defect found in cases of malnutrition. This defect may be found as a brown line running as a rule across the incisors, and it may be the canines or it may be a brown patch of varying size and intensity of colouring, though it is usually a rusty brown. Very commonly it is associated with marked opacity of the enamel, and it seems to indicate a somewhat severe degree of disturbance of the nutrition.

Placing the frequency of occurrence in the poor-class and the better-class children side by side, the following is the result given in percentages:—

	In 281 poor-class children.	In 122 good-class children.
Opaque chalky enamel	28·5%	9%
Brown line of Retzius	13·0%	1 case.
Hypoplasia	8·5%	5%
Honeycombed teeth	2·5%	0

As already shown, out of 281 poor children, 114, or 40 per cent., had defective enamel, as compared with 13 per cent. amongst the better-class children. Taking the 114 cases with defective enamel among the poorer-class children there was found—

Chalky enamel	80 = 70%	Typical hypoplasia ...	24 = 21%
Brown lines of Retzius	38 = 33%	Honeycombed teeth...	7 = 6%

It is of great importance to note the teeth most commonly affected. In the children where the enamel was opaque and chalky the teeth were affected in the following order of frequency.

Central incisors...	78%	Premolars	20%
Lateral incisors...	55%	First molars	10%
Canines	30%	Second molars	5%

These figures are accurate except in the case of the first and second molars. The first molars were frequently badly decayed or the tooth had been extracted. The second molars in many of these cases had not yet been erupted.

In 38 cases when the teeth showed the brown lines of Retzius—

Central incisors affected in	36=95%	Canines affected in	5=13%
Lateral ,, ,,	11=29%	First molars, 1 case.	

It is important to note that in hypoplasia and in cases where the chalky patches and the brown lines of Retzius were found the teeth which suffered chiefly were, first, the central incisors; secondly, the lateral incisors; and, thirdly, the canines in this order of frequency. Reference to the diagram will show that the calcification of the enamel of the crowns of these teeth goes on during the first two years of the child's life. So that these defects are due to errors of nutrition affecting the child at this early period when the rate of growth, and notably that of the brain, is relatively enormous. Rickety conditions are especially operative at this period. Hypoplasia, as we have seen, affects the incisors, canines, and first molars. Much more rarely the premolars and the second molars are affected by hypoplastic changes. White patches in the enamel, one of the commonest signs of malnutrition, are, however, fairly commonly found in the premolars and second molars, which must be due to conditions operating on the child between the second and the sixth year.

ANGINA PECTORIS:

CHANGES IN ELECTROCARDIOGRAM DURING PAROXYSM.

BY GUY BOUSFIELD, M.B., B.S. LOND.,
LIEUTENANT, R.A.F.

THE accompanying curves were taken from a patient who had aortic disease. There was an old history of syphilis, scarlet fever, and several attacks of rheumatism. The typical diastolic murmur and water-hammer pulse were present.

As I was about to photograph the first lead the patient had an attack of angina pectoris, to seizures of which he had been subject. Having hastily sent for amyl nitrite capsules, I felt justified in proceeding with the cardiogram until the remedy arrived. Under these conditions Plate 1 was taken. Plate 2 was obtained from the same patient when the attack had completely subsided.

FIG. 1.

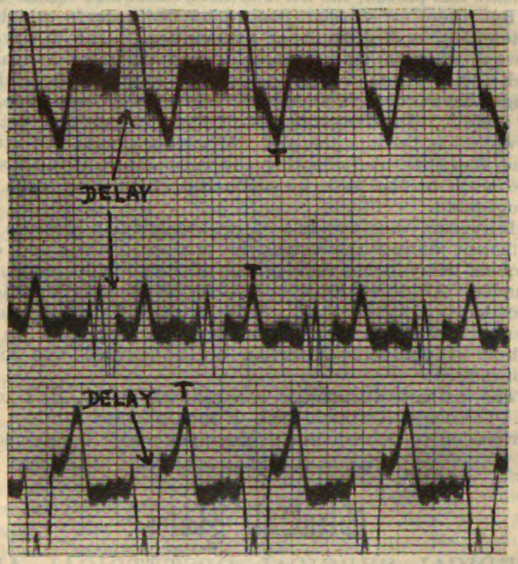

FIG. 2.

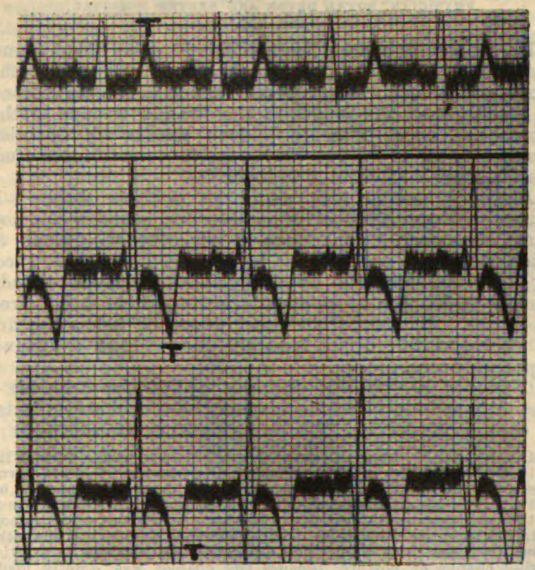

Curves in Plate 1 are quite typical of those obtained in severe cases of aortic disease, showing marked delay in the transmission of the nervous impulse through the right branch of the auriculo-ventricular bundle. It is quite clear,

however, that some factor other than the aortic lesion was concerned in the production of this delay; this is shown by the fact that when the anginal attack had subsided no delay in the nervous transmission occurred. (See Plate 2.)

Severe aortic disease is known to be associated with high intraventricular pressure. One of the theories of the causation of angina is that the attack is due to vaso-motor spasm, and the resulting increase of peripheral resistance raises the general blood pressure, and consequently the intraventricular pressure. The above curve would appear to confirm this in a measure, for the patient was not thoroughly "at home" in the cardiograph room, and fear of the unknown was probably sufficient to produce the rise of blood pressure which precipitated the attack. Clearly, as the second plate shows, the aortic lesion alone was not responsible for the delay in the bundle, for here, when the seizure had passed, the nervous disturbance also vanished.

But there is another feature of the records which is interesting and difficult of explanation. The T wave is always erect in lead 2 of a cardiogram from a healthy individual. Here, during an attack of angina pectoris which might have proved fatal, wave T was *erect*. Compare lead 2 of Plate 2. The dangerous attack had now subsided, yet the T wave has become *inverted*. Whatever caused the attack was, therefore, also affecting the musculature at the base of the aorta or the path by which the stimulating wave was propagated.

It appears that the rise of intraventricular pressure was sufficient during the attack to produce distress and consequent delay in the right branch of the auriculo-ventricular bundle. All three leads in Plate 1 demonstrate this delay excellently. Again, the disturbance was sufficient to cause a profound effect on the musculature at the aortic base, to the extent of producing inversion of the wave T due to its contraction.

The patient was under the care of Dr. C. R. Box in St. Thomas's Hospital, and I am indebted to him for permission to publish the photographs which I obtained.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

DISTANTLY AUDIBLE HEART SOUNDS.

BY W. GORDON, M.D. CANTAB., F.R.C.P. LOND.,
PHYSICIAN, ROYAL DEVON AND EXETER HOSPITAL.

BY "distantly audible heart sounds" I mean heart sounds audible at a distance from the chest wall without a stethoscope, and, for practical purposes, I would define the distance as greater than the length of the straight wooden stethoscope—i.e., about 7 inches. Such sounds are doubtless familiar to all of us, but they seem to deserve more study than has yet been devoted to them.

Distantly audible first sound in Graves's disease.—In Graves's disease a distantly audible first sound is common, much commoner, I think, than in any other condition. So often have I met with it that now, when I notice it, I look for other indications of hyperthyroidism. Graves related a case in which the heart sounds were audible 4 feet from the chest. In one of the cases described below the first sound was audible 5 feet from the chest. Such a distance is probably rare.

Change of posture and distantly audible heart sounds.—Distantly audible heart sounds may be remarkably affected by change of posture. The following illustrate this:—

Mrs. A., aged 31, a typical case of Graves's disease, with a pulse of 120, and a cardiac dullness reaching 6 inches leftwards from the mid-sternal line in the erect position (corresponding with the limit of the h.a.b.), had a very pronounced first sound as well as a slight systolic murmur. In the erect posture the first sound was audible without a stethoscope 19 inches from the chest wall; in the recumbent posture it was audible 5 feet from the chest wall. The difference was not due to exertion during change of posture, because the change was quietly made, and when the erect position was resumed the distance of audibility again decreased. My friend Dr. J. Raglan Thomas confirmed these measurements.

Mr. B., aged 28, with a heart dullness almost normal in area in the erect position, a short presystolic apical murmur and a basal aortic diastolic, had a very marked apical first sound. This first sound was audible without a stethoscope 14 inches from the chest wall in the erect position. In the recumbent position it could be heard 30 inches from the chest wall.

These changes in distantly audible heart sounds, so obvious and with limits of audibility so easily measured, furnish a valuable (because incontestable) addition to what has been so repeatedly reported in respect of the influence of bodily posture on cardiac physical signs. They furnish further proof, if such be needed, of the contention that no description of cardiac physical signs is scientifically accurate which omits a statement of the bodily posture at the time of observation. Heart sounds are rather out of fashion just now and, a little while ago, the shade of Laennec might have been excused for some discouragement. However, as aortic regurgitation and mitral stenosis have happily been rediscovered, it may be worth while continuing to describe heart sounds.

It is good to notice that descriptions of cardiac conditions are beginning to appear in which the posture of observation is stated. Perhaps the observers, like Laennec and Graves, have used the more accurate straight wooden stethoscope.

A CASE OF PROLONGED ARTIFICIAL FEEDING.

BY J. BATTY TUKE, M.D., F.R.C.P. EDIN.,
NEW SAUGHTON HALL, POLTON, MIDLOTHIAN.

THE following case of artificial feeding is interesting on account of the duration of treatment.

A woman, aged 57, single, was admitted on August 24th, 1908. History: For five years has been suffering from delusions of a religious nature and hallucinations of hearing—e.g., imagines that she is the Bride of Christ, and gets direct messages from Him, telling her to perform certain actions which she is bound to obey. In consequence of one of these messages she set fire to the house she was living in before being brought here. Up till August 29th, 1909, she took her food fairly well, though somewhat erratically, one day taking nothing but solids, the next nothing but fluids; on this day, however, she received a message from Christ commanding her not to take food or drink of any kind, and up to present date (September, 1918) not even a drop of water has voluntarily passed her lips. For the past nine years she has been fed regularly three times a day by the mouth with a feeding-tube, being perfectly quiescent during the operation. When the artificial feeding was first commenced she weighed 6 st.; this rose in two months to 6 st. 7 lb., and since then it has never varied more than a pound or two up or down. Her bodily health is, and always has been, absolutely good; she has never had a day's illness, has been out regularly, and employs her time in the house reading, writing, and doing useful and fancy sewing.

To all appearances the patient may, if she has not already done so, create a record for the duration of continuous artificial feeding.

A CASE OF ACUTE ASCENDING PARALYSIS.

BY W. WADDELL, M.B., CH.B. EDIN.

IN the following case the past history was unimportant, with the exception of an attack of measles at the age of nine.

The patient was a woman, aged 28. At 3 P.M., on April 18th, she began to feel pains in the back and head and tingling in both legs. When seen at 8 P.M. on the same day there was definite weakness in both legs; the left leg, the patient stated, became weak first. The power of standing was lost. Knee-jerks were absent. The patient was perspiring freely. The following morning, at 10 A.M., there was complete paralysis of both legs, with relaxation of the muscles. At 3 P.M. on the 19th there was paralysis of the muscles of the pelvis, loins, abdomen, and weakness in the muscles of the thorax and those of right forearm and hand. There was tenderness of muscles, a firm touch could be perceived anywhere, but perception of painful impressions and of heat and cold was delayed. Cutaneous reflex action was lost. There was no wasting of muscles, and the electrical reactions were unimpaired. Temperature 98·2° F. Pulse 78.

There was mental dullness, and later in the day absolute paralysis of the muscles of the thorax, both arms, and diaphragm; the neck muscles had also begun to suffer. Speech became indistinct, and the patient soon passed into a state of stupor and died at 5 A.M. on the 20th.

The muscles, nerves, and spinal cord appeared on naked-eye examination to be free from disease. There were degenerative changes in the cells of the anterior cornua, with slight vascular engorgement.

Umtata, Cape Province, South Africa.

THE Devon County Council have arranged for the provision of a home for mentally defective boys at Exmouth.

THE Council of Bristol University is offering to the general public during the coming winter free courses of instruction in English literature, chemistry, and geology.

Reviews and Notices of Books.

Thyroid and Thymus. By ANDRÉ CROTTI, M.D., F.A.C.S., LL.D. With 96 illustrations and 33 plates in colours. Philadelphia and New York: Lea and Febiger. 1918. Pp. 567. Price $10.

To the publishers of this large work we offer our congratulations. The book is a beautiful specimen of the typographic art, the paper and binding are of the best, and the execution and reproduction of the coloured illustrations, which are numerous, call for special praise. It is, indeed, an édition de luxe, and few authors have had the good fortune to have their writings presented to the reading public in such an attractive way. The author states that the work is the result of 17 years' experience in the field of goitre pathology in Switzerland and the United States, and expresses his indebtedness to Professor Henry Stilling, of Lausanne, to whom he owes much encouragement and self-confidence, and to Professor Theodor Kocher, who has given him inspiration and example. He also states that, in addition to personal experience in the study of the thyroid and thymus glands, he has gathered all that he considers of value from the enormous amount of French, Italian, German, and English literature on the subject, and that he has endeavoured in his recital of sources and authorities to give credit where credit is due.

From the title-page we learn that the author was formerly professor of clinical surgery and associate professor of anatomy at Ohio State University College of Medicine, and surgeon to Grant and Children's Hospitals, Columbus, Ohio. We may conclude that his personal experience has been more surgical than medical, and that what he has to say about the surgical aspect of diseases of the thyroid and thymus will be the more valuable part of the book. About one-fifth of the book is devoted to the consideration of operative methods and technique, and most of the illustrations and coloured plates are connected with this part of the subject. Indeed, the medical part of the book, although occupying four-fifths of its pages, appears to have been written chiefly to lead up to the subject of surgical treatment. It is difficult to understand what the author means when he says that he has endeavoured in his recital of names and authorities to give credit where credit is due. The book, indeed, bristles with names, but references to published writings are conspicuous by their absence. The absence of references, of a bibliography, and of an index of names is one of the greatest defects of the book. When an author is quoted no clue is given as to the work from which the quotation is made. What is worse, we find whole passages literally translated from Professor Ewald's well-known monograph incorporated in the text without any acknowledgment at all. When names are given they are not always correct; thus, we find Perry for Parry, Madden for Hadden, Hutchinson for Hutchison, Schöefer for Schäfer, Buscham for Buschan, Fomeris for Forneris, &c.

The introductory chapters on anatomy, physiology, and biological chemistry of the thyroid and pathology of thyroid tumours are, on the whole, adequate. It is incorrectly stated, however, that "normally the human thyroid gland contains 1 to 9 grams of thyreoglobulin," corresponding to 5 to 45 mg. of iodine. The actual amount is from 2 to 8 mg. "Everyone knows," says the author, "Halstead's classical experiment: If a portion of the thyroid is removed, the remaining portion of the gland reacts by secondary hypertrophy." In a treatise published in 1918, the fact should have been mentioned that in 1914 Halstead published a paper entitled "Reconsideration of the Question of Experimental Hypertrophy of the Thyroid Gland," stating that his former experiments had been fallacious. Hunnicott in the same year published a paper demonstrating the absence of hyperplasia of the remainder of the thyroid in dogs after piecemeal removal of this gland. In spite of this the author, not only here but elsewhere in the book, refers to Halstead's old experiment, as if it were still an accepted fact and draws conclusions from it on that supposition.

The chapter on inflammations of the thyroid is an interesting one. We may remark that it was at the commencement of the nineteenth century, not in the eighteenth as the author states, that descriptions of thyroiditis were first given by Carron, Walther, and others. In the description of woody thyroiditis we notice a good many unnecessary repetitions, and there is a tendency to repetition throughout the book. Here we read: "It was Riedel who in 1896 first described a form of thyroiditis which he called 'eisenharte strumitis' or 'iron-hard strumitis.'" "On account of the extremely hard consistence of the tumour Riedel called it 'eisenharte strumitis.'" "This form of thyroiditis called by Riedel 'eisenharte strumitis' or iron-hard strumitis." "The tumour is absolutely hard like iron or wood, hence its name." The term does not call for such insistence.

The so-called parasitic thyroiditis of Chagas is described. In this disease the enlargement of the thyroid does not appear to be the main part of the illness. We think its relation to chronic goitre to be very doubtful. A naïve remark is made regarding hydatid cyst of the thyroid: "Clinically the diagnosis of hydatid cyst is seldom made, as the only symptom pathognomonic of its presence—namely, the 'hydatid fremitus,' has never been perceived."

The author has given a good account of the anatomico-pathological relations of goitre to the surrounding structures. Chapter VI. and the succeeding chapters on the various forms of goitre and their clinical symptoms are well written; in this section of the book the author is at his best. Here we come across a curious remark: "A great many goitres in their early stage give to the neck a soft roundness called 'swan-neck.'" The subject of myxœdema is started in the middle of a chapter on the clinical aspect of malignant goitres, and is continued along with that of cretinism in the three following chapters. Whether the author has himself seen little or nothing of myxœdema and cretinism we are unable to say, but he gives what seems to us a very poor and inadequate description of these most interesting diseases. Although there are 96 illustrations in the book there is not a typical picture given either of myxœdema or cretinism. True, there is an illustration on p. 199 labelled "Spontaneous adult hypothyroidism," but it shows nothing in the least characteristic of myxœdema, and might be more appropriately labelled "Portrait of a lady." The illustration on p. 204 labelled "Spontaneous infantile hypothyroidism," as far as we can see, shows nothing but obesity. The author is sometimes unconsciously humorous, as when he says: "The hands and feet are thick and clumsy; the fingers have the shape of small round sausages; hence the name 'spade hands' of Gull." A chapter on thyroid insufficiency serves to illustrate the danger of seeing the condition in almost every person. The author gives as symptoms in children lack of appetite and constipation, but admits subsequently that it would be an error to claim that every constipation is due to thyroid insufficiency! There is next a long and interesting chapter on the etiology of endemic goitre and cretinism, which is supplied by the author's wife. The antiquated and third-hand information, however, regarding the prevalence of goitre in America on p. 225 is not what one expects to find in an up-to-date treatise published in the United States. In the chapter on the medical treatment of goitre it is stated that Coindet first used iodine in 1829. Coindet's work appeared in 1820 and he began the use of iodine in 1819. The author says: "We may say that the medical treatment of simple goitre is contained in this one word iodin." These are exactly the words of Ewald: "Die medikamentöse Behandlung der Struma lässt sich in ein Wort zusammenfassen: Jod." The thyroid treatment of myxœdema is an interesting chapter in the history of therapeutics, but all the author has to say about its evolution is that "after a long period of experiments and trials it is now universally admitted that the ingestion method is the easiest and most effective treatment in thyroid insufficiency."

The section of the book dealing with the medical aspect of exophthalmic goitre occupies 127 pages, but although so much space is covered there is no account given of the morbid anatomy of the disease except as it affects the thyroid. The relation of enlargement of the thymus to the disease, however, is mentioned on p. 392. The description of the symptoms of this extremely interesting disease shows little evidence of personal clinical knowledge on the part of the author. With regard to tremor, the author says: "According to Sattler, who went over the literature of the subject very carefully, tremor is present in 9 per cent. of all the cases of Basedow's disease." No comment is made on this

strange statement, although it has been already stated that tremor is one of the cardinal features of the disease. In the account of the nervous and mental symptoms we read: "They may enter into the most paroxystic fits of rage; some live in a state of perpetual anger. They quarrel with their most intimate friends. Their love for their own relatives becomes less and less. A great number of these patients are divorced or separated women, and some of them are simply abandoned by their husbands." Further on we read: "Not so infrequently the exophthalmic goitre will terminate by an acute delirium. It takes several nurses to hold him in bed. He talks incoherently about his occupation or profession. If he is a farmer he may be talking about pitching hay; if he is a lawyer about defending a suit; and if a housekeeper about some feature of housekeeping." We have never heard even of cases like these, and we are informed by probably the best known specialist in this country that, as far as he knew, none of his patients suffering from exophthalmic goitre had been divorced or separated.

There is a chapter on "the etiology of Graves disease," the conclusion of which is that "Graves disease is a form of toxic thyroiditis," and then we come to the important question of treatment and whether it is to be medical or surgical. Into this question Professor Crotti enters at some length. He is all for operation. The two points for consideration, it seems to us, are: (1) Is it safe, and (2) does it cure. We ourselves are coming to the conclusion that operations can be safely done under local anæsthesia and expert surgical technique. We find that patients are benefited in various degrees, but that the degree of benefit obtained depends on the amount of gland left being just enough and not too much. The long lists of cures which are again and again put forward by some surgeons are of little value. Only time will show how far patients are capable of being cured by operation.

The remainder of the book is concerned mainly with surgical technique. Professor Crotti favours resection in preference to excision or enucleation, and calls it the method of choice. He seems to think that excision, the complete removal of one lobe, has been more or less abandoned as exposing too easily to injury the inferior laryngeal nerves and parathyroids, and that for the same reason enucleation or intracapsular excision should be discarded. The author seems to us to have too great a fear of the consequences of damaging the parathyroids. He says gravely: "Not very long ago saw one of our foremost surgeons, when performing this intracapsular excision, come in contact with a parathyroid, crush it with a hemostat, and become aware of it only when his attention was called to it by one of his assistants." The sequel of this catastrophe is not mentioned, and we should be indeed surprised if anything untoward happened. With regard to ligature of the thyroid arteries as a method of treatment of Graves's disease, we should have thought most surgeons had by this time realised its futility. It had its vogue, but its vogue is passed. If an operation is done at all, it should be removal of thyroid tissue. Time is simply wasted by performing ligature operations. As for sympathectomy, that is surely only of historical interest in relation to diseases of the thyroid. The author advocates, and we think rightly, the use of local anæsthesia in operating on cases of thyrotoxic goitres, but we do not think the cause of local anæsthesia will be forwarded by his reference to "the yells, cries, and sometimes the insults which the patient pours out on the surgeon who is endeavouring to do his best," which, he adds, "are very trying to the nervous system of the operator." Professor Crotti's experiences have been peculiar, and we can only conclude that local anæsthesia has been very imperfectly carried out in such cases. This conclusion is confirmed when we read the description of the author's method for producing local anæsthesia. He advises the use of a 2 c.cm. syringe with a fine needle for injection! The chapter on local anæsthesia is strangely behind present-day technique. It usually requires about 200 c.cm. of solution to produce adequate local anæsthesia in a thyroid operation. How with a 2 c.cm. syringe to introduce this amount of fluid subcutaneously may be left to the reader's imagination.

The last chapters of the book deal with the thymus gland, and only occupy 23 pages out of 558. There is not, indeed, a great deal to be said about thymus diseases, and what is said is sufficient as regards present-day knowledge. There is one remarkable statement made on p. 555 to which we must draw attention. The author there says that during the past few years he has been removing the thymus in every goitre case that has come his way. In every case, he says, as soon as thyroidectomy is terminated he systematically explores the mediastinum, and whenever thymus is found it is removed! We should like to have learnt more about these operations and their results. How many such operations have been performed and how much thymus is removed?

The book is written in a breezy style, but some of the expressions used by the author sound strange to the English reader, such as "the disease evoluates"; "paroxystic fits"; "a fright will not feaze this one"; "the baby will refuse to nurse"; "a gangue." The index at the end of the book is inadequate. In spite of imperfections the book is of considerable value, and if revised and supplemented by references and bibliography, as we hope it may be in a second edition, its value would be much enhanced. It is with this idea in view that we give space for so detailed a review.

Clinical Gynæcology. By JAMES C. WOOD, A.M., M.D., F.A.C.S. Philadelphia: Boericke and Tafel. 1917. Pp. xxxviii.–236. Price $2.00.

THIS monograph is based upon a series of clinical lectures delivered by Dr. Wood to the students of the Cleveland-Pulte Medical College, and deals with the application of homœopathic principles to gynæcological practice. The plea is set out for a better understanding of Hahnemann's system in the hope that it may be found to bridge the chasm between the regular, homœopathic and eclectic schools of medical thought in America. Quaint claims are made by the author: for instance, Hahnemann is hailed as the forerunner of Pasteur, of Basedow, and of Jung. Widal's agglutination test is called to witness to the efficacy of *baptisia* as a specific for enteric, and Wright's opsonins to support the place of sulphur as a specific for *Staphylococcus aureus* infections and of phosphorus for tuberculous disease. The book regarded as a treatise on clinical gynæcology is generously catholic in its outlook; barely 8 of the 15 chapters are devoted to purely gynæcological topics, and in these Dr. Wood does not hesitate to describe such conditions in the male as acute intestinal obstruction, pyloric stenosis, and a visceroptotic stomach. The remaining chapters are devoted to gastric ulcer, gastro-intestinal auto-intoxication, and mucous entero-colitis; reflex and toxic epilepsy; and exophthalmic goitre. It is recorded that a patient in the acute stage of the last-named ailment underwent the following operations: curettage, freeing of adhesions of the clitoris, dilatation of the rectum and removal of rectal papillæ, ovariotomy, and, finally, ventro-suspension. Dr. Wood bases this surgical therapy upon the hypothesis of exophthalmic goitre as a "reflex neurosis," and remarks, "we live in an age of multiple operations."

Dr. Wood has much to say which is interesting, but the light-hearted way in which he dilates the uterus and rectum and performs small and large operations in the genital sphere for almost all the cases he describes will, we fear, create very erroneous impressions in the minds of his students. As a text-book his work has no claim to serious consideration.

Modern Methods in the Diagnosis and Treatment of Phthisis, with Special Reference to Tuberculin. By JAMES T. MACMANUS, M.B., B.Ch. N.U.I. London: John Bale, Sons, and Danielsson. 1918. Pp. 64. Price 2*s.* 6*d.*

WITHIN the limit which he has assigned himself Dr. Macmanus has put together a very readable account of the methods at present in use for the diagnosis of tuberculous disease of the lung, drawing largely on the work of others, but stating their results fairly and adding comments from his own experience. This part of his book may be read with profit by all engaged in special work. Modern methods of treatment for the author begin and end with tuberculin, and here again the author states temperately his own experience and that of others. But since hygienic treatment is dismissed in a sentence, the expectation raised by the title is not fully satisfied. The reader will find tiresome the mis-spelling of many proper names.

THE LANCET.

LONDON: SATURDAY, OCTOBER 5, 1918.

Preventive Measures against Lice-borne Diseases.

IN an instructive lecture at the Royal Society of Medicine on the Prevention and Arrest of Lice-borne Diseases, which was published recently in THE LANCET,[1] Colonel W. HUNTER referred in some detail to facts and figures which he had obtained regarding the epidemics of typhus and relapsing fever which ravaged Serbia in the early part of 1915. No part of the lecture will be read with greater interest than that in which the rapid decline of those formidable outbreaks is described, and associated with the introduction on a large and systematic scale of simple measures for the destruction of lice, together with the prevention of movements of troops which would lead to their re-infection from the civil population. With the success which attended these measures the British medical mission sent out under Colonel HUNTER'S direction must always be gratefully associated. It was particularly to the credit of the mission that its energies were not dissipated in mere local palliative measures, but were concentrated on enforcing the recognition and general application of first principles of prevention, such as Colonel HUNTER has emphasised. It is well to recall these epidemics at the present time, as they illustrated in a most forceful and disastrous fashion the danger to important military operations which may result from the uncontrolled spread of typhus and relapsing fever, particularly when the troops exposed to infection are mixed with a civil population suffering from destitution and malnutrition, thus affording the most favourable soil for the dissemination of these diseases. At the present stage of the war, when we consider the conditions reported from Russia, from the Balkans, and even in parts of the Central Empires themselves, and remember that the winter has yet to come, recurrences of typhus or relapsing fever on the Serbian scale seem far from improbable, and they may well occur in circumstances which bring the Allied forces into the closest contact with the infection.

The almost negligible extent to which British forces have so far been affected by these diseases, at any period of the war and on any front, is as remarkable as it has been satisfactory, and may be attributed to a collection of causes. It has seldom happened that our fighting forces have been operating in areas stricken with epidemic typhus. Individual cases or groups of cases, when they occurred, have been very effectively dealt with by isolation, segregation of contacts, and thorough local louse destruction—or disinfestation, if we adopt the word which is now often used to distinguish those measures of disinfection which are sufficient for destroying parasites. The infection of these diseases has thus not been allowed the chance of spreading far afield, although the forces concerned may have included large numbers of soldiers infested by lice. As the experience of trench fever has shown how extensively lice-borne disease can be spread, even with the precautions taken on the Western front, it might be argued that the escape of the British forces can be attributed solely to the measures taken to prevent access of the specific infections. This, however, is unlikely, and other contributory factors must be remembered. The great epidemics of typhus and relapsing fever have frequently been closely associated with famine, and the view has often been expressed that a well-fed British soldier has normally a high degree of natural immunity against these diseases. This view deserves consideration, though there is some evidence in a contrary sense; for example, the heavy incidence of typhus on the attendants in Russian prisoners' camps in 1915.[2] The effect of the great efforts which have been made to keep down lousiness in the Army as a whole has, however, unquestionably been one of the main causes of safety. The record of all the British Armies in this matter, including particularly those on the West, has been one of steady improvement and progress, to which the unsparing labours of all ranks of the specialist sanitary service, as well as of experts at home, have notably contributed.

All kinds of devices are now used in combating lousiness, including the method of disinfecting clothing, blankets, and kits with current steam, on the proved efficacy of which Colonel HUNTER lays so much stress, both in regard to clothing in bulk, as treated in Egypt by the railway disinfecting vans, and clothing in small lots, as dealt with in Serbia by the barrel disinfector. Other effective methods are provided by special huts and dug-outs into which circulating hot air is introduced, while the experience of many shows how much can be done with no other materials than a hot iron, petrol, soap, and a wire brush. The nature and details of these different methods are now well known, at least in the Army, where they are described in various official circulars, and demonstrated to all officers going through courses of sanitary instruction. In louse destruction it is well always to keep in mind that the difficulties do not lie in the destruction of lice and their eggs, which can be accomplished with relative ease and needs no higher temperature than 55° C., but with the organisation of the methods of cleansing and disinfestation. The latter must be applied at the same time to all the group of men concerned and all their belongings, their re-infestation must be prevented, and the process must be systematically repeated. These requirements, simple as they appear, are most difficult to fulfil in actual conditions of a campaign, and the medical officer who is to secure their fulfilment should keep in mind the enthusiasm and persistence which Colonel HUNTER and his fellow workers infused into the methods which they pressed in the Eastern areas in the earlier years of the war, and which were so largely responsible for their success.

The Conditions of the Royal Air Force Medical Service.

THE conditions of the Royal Air Force Medical Service, which were published in THE LANCET, will have been read with satisfaction by the medical profession, for they represent an improvement from the scientific point of view upon any terms which have hitherto been offered to the medical profession when engaged on naval, military, civil, or administrative work. These conditions doubtless were not arrived at without considerable effort, and those who bore the brunt of the struggle deserve the thanks of their professional brethren. They have made it possible for the Royal Air Force to possess a medical service which should be an effective safeguard against many of the dangers inherent in aviation, whether as an athletic achievement or a fighting activity, and they have done this by securing free play in greater measure to scientific ideals.

The partition of the medical work of the Royal Air Force into two main branches, one having the care of the effective personnel and the other of the non-effective, makes proper room for the allocation of the medical officers to occupations for which they are fitted. The care of the effective personnel will be undertaken by officers whose work has lain on the hygienic and preventive side of medicine, while it is here also that the psychologist will have his fruitful field of activity, for the selection of the flying officer takes into consideration much more than the physiological attributes of the candidate, as Captain T. S. RIPPON and the late Lieutenant E. G. MANUEL showed in their report to our columns.[1] For while it is absolutely necessary that there should be no doubt whatever concerning the respiratory and circulatory systems of the flying officer, and while his special senses, particularly the visual reflex, play an important part in his success, the flying temperament will be an asset of incommensurable value, and one whose ascertainment will fall to a great extent upon the officers of the Royal Air Force Medical Service working in the division of the effective personnel. It may be that this temperament cannot be detected with certainty until after selection and trial, but it must be looked for. The care of the non-effective personnel is the second great division of the work of the Royal Air Force Medical Service. This curative side provides room in the service for experts in the surgical treatment of the eye, throat, nose, ear, and plastic surgery, for neurologists, and practitioners in every province of remedial therapeutics. It is, we trust, the intention of the authorities to place each of these main divisions of the Royal Air Force Medical Service under a director having administrative control of his division and direct access to the Director-General of the Force—for this is how, we hope, the Medical Administrator will be styled, in consonance with the title employed in the sister services.

Special attention may well be called to the fact that throughout the service a second principle prevails, almost equally important for scientific efficiency with the principle of fitting the employed with suitable employment—and that is promotion by merit. The third general condition of medical service in the Royal Air Force runs:—

> Subject to the exigencies of the Service, a medical officer will be selected for, and eventually allocated to, work in the subdivision for which his ability best suits him. Since, however, the success of any special work in the Air Force will depend upon a sound knowledge of the conditions of life of the effective personnel, medical officers will not be earmarked for one of the special subdivisions of the Medical Service until selected for the higher or Grade A pay, vide Appendix II.

And the fifteenth general condition runs:—

> Promotion to ranks above that of Captain in the R.A.F. Medical Service will be by selection to fill vacancies in the establishment.

Medical men should realise that the officers in the service will, in accordance with these paragraphs, be entrusted with subdivisions of medicine or surgery where they have shown special knowledge, while the system of charge-pay in vogue in the medical services of the Navy and Army has been replaced in the medical service of the Royal Air Force by a system of special merit pay. When an officer has shown specially good work he is rewarded by selection for Grade A pay, and he will draw this pay for a probationary year, and then, being confirmed in Grade A, will continue to draw it, however employed, until he obtains promotion to a higher rank. Then he has to make good again, and by the recurring incentives the powers of concentration are developed and energies regularly stimulated.

[1] THE LANCET, Sept. 28th, p. 411.

Filling up the Ranks.

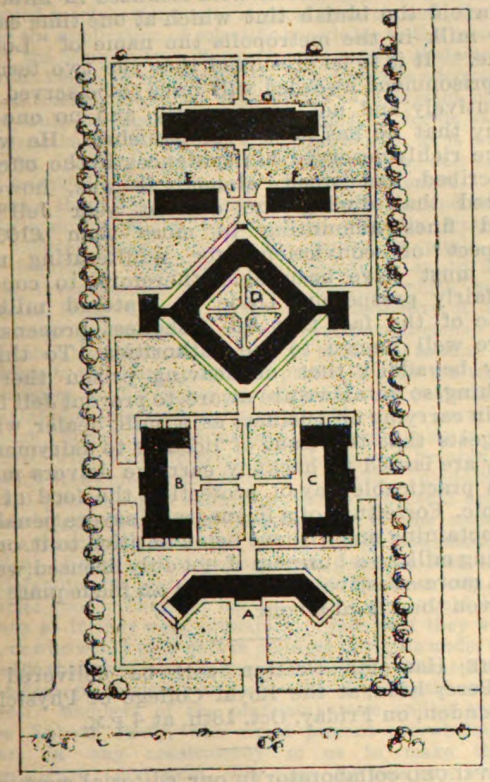
THE winter session opened on Tuesday last at the hospital medical schools in London, although only at a few did the exigencies of war permit of the usual formal address and celebration. Speaking at the Middlesex Hospital Dr. C. H. BROWNING dwelt upon the great future of medicine as an applied science. At King's College Sir WATSON CHEYNE emphasised the complementary aspect of the human element in medical practice. There is, in truth, room for minds of many bents among those who take the oath of HIPPOCRATES. Returns of the new entries at the medical schools have not yet all come in, but enough to show what is probably a record number for the year which has begun. Many of the classes for ancillary studies at University College have more than doubled in size, and Miss ALDRICH-BLAKE welcomed a hundred new women students at the London School of Medicine for Women. It is little wonder that the present moment should attract both men and women into the healing profession. However soon the war may be over, the problem of the restoration of the disabled combatant is already sufficient to occupy the best medical hands and brains for at least twenty years ahead, while the record of service in the field for the fourth year of war, which we print on another page, contains an inspiring account of self-sacrificing effort in many lands. Honours have been conferred upon many of the survivors, but the ranks have been sadly depleted, one large school alone recording nearly a hundred past students killed in action since the beginning of the war. Large as the entry of students may be, it will not be more than sufficient to fill up the ranks.

Annotations.

"Ne quid nimis."

A MODEL HEALTH CENTRE.

AT the meeting of medical men at Steinway Hall on Oct. 1st, which we report in another column, Dr. Addison, Minister of Reconstruction, said that the general scheme for the unification of public health activities is now being considered by the War Cabinet. Here he gave his medical audience no further hint as to the tenour of the impending Ministry of Health Bill, although at the Pharmaceutical Society on the following day he spoke of the growth of a series of specialist and technical services around medicine and pharmacy which may before long present different problems, both of training and personnel. Sir Bertrand Dawson has now reprinted[1] his Cavendish lectures, and the pamphlet will serve a useful purpose in concentrating attention on what must be the essential parts of any scheme hoping to introduce harmony into the medical services of the country. At the same time Sir Bertrand Dawson goes into interesting detail in describing a model health centre, its arrangement and purpose, giving a large scale plan elaborated by Major Biddulph-Pinchard, R.A.F. This plan, of which we reproduce here the key, represents a health centre



serving a town of about 30,000 inhabitants, drawn from an imaginary aeroplane 300 feet above the ground. The distance from the edge of the town to the entrance of the health centre is supposed to be about a quarter of a mile. The plan embodies the conception that the furtherance as well as the restoration of health needs provision by the health authorities, and that both are the responsible concern of the medical profession. The details are as follows:—

Clinic A provides accommodation for ten doctors, with waiting rooms, an examination and operating room, radiographic institute, laboratory, dispensary, rooms for keeping records of cases, and a common room where the doctors could meet in friendly consultation. Behind this curative clinic are the preventive clinics, B and C. Here would be located services for maternity care, infant welfare, school hygiene, dentistry, and any others which the special needs of the town might require. Behind this is a diamond-shaped hutted hospital, D, with two annexes. The wards vary in size and are allotted to different purposes; the verandahs attached to them make provision for open air treatment. One of the annexes provides accommodation for an operating theatre with its subsidiary equipment. E is allotted to hydrotherapy and F to massage, passive exercises, and electrical treatments. G is a fully equipped gymnasium for physical culture and for developmental and remedial exercises.

All the buildings are to be constructed on the hutted plan, Sir Bertrand Dawson holding that the progress of knowledge and the changing needs of the community make it important to avoid the permanency of bricks and mortar. A playing ground forms an important part of the author's scheme. Here exercises and games designed to secure physical fitness and beauty and to remedy defects would be directed by skilled instructors. Here, too, he would provide for our national games under conditions of true sportsmanship and detached from undesirable overgrowths. The playing grounds are not to be places in which to loll about in idleness, but rather for pleasurable and ordered occupation, where body and mind are taught to work together in the happiness of concentrated effort. In cities Sir Bertrand Dawson would place the clinics alone in convenient numbers within the town, removing hospital and its adjacent services with the playing grounds to the outskirts. He would discard the practice of building complete hospitals within towns. His scheme, which before the war would have appeared merely visionary, is certainly capable of practical realisation if it commends itself generally to the medical profession.

THE MIGRATION OF METALLIC BODIES IN THE CIRCULATORY CURRENT.

A NUMBER of cases have now been recorded of migration of projectiles in the circulatory current. Bullets have been carried from the left side of the heart into the aorta and then lodged in a large artery, such as the axillary or femoral, arresting the circulation and producing gangrene of the limb. In the venous system the problem of migration is not so simple; the projectile may migrate either with or against the blood current. A case has been recorded in which a bullet entered the right ventricle and gained the origin of the iliac vein, and one in which a shrapnel bullet, first situated in the right auricle, was found an hour later in the triangle of Scarpa, the patient having raised himself; and then, after a few minutes in the dorsal decubitus position, it was found on a level with the sacro-iliac synchondrosis. Usually, however, the migration is in the direction of the blood current. Thus, in a wounded soldier radiologic examination showed a projectile first in the iliac region, then in the right auricle. At a meeting of the Académie de Médecine of Paris, M. Ch. Achard and M. Léon Binet reported a number of experiments which they had made on the migration of metallic bodies in the circulation of dogs. Grains of lead introduced into large arteries rapidly gained the periphery, even when the limb was

elevated and the movement therefore opposed by gravity. In veins, on the other hand, gravity exercised an important influence. Four grains of lead and four of rice were introduced separately into the femoral vein of a dog in the horizontal position and driven onwards by an injection of saline solution. When the animal was killed 15 minutes later the grains of rice were found in the right lung and the grains of lead in the abdomen, engaged in the termination of the hepatic vein. Into the left femoral vein of a dog lying on a table inclined at an angle of 35° with the head above, 2 grains of rice and 2 of lead were introduced. One grain of rice was found in the right lung and the other in the right heart; the 2 grains of lead were found in the pelvic veins on the left side of the bladder. Thus in the veins light foreign bodies are carried with the current and against gravity, heavy bodies the reverse. But there are other factors in migration—the volume, form, and contour of the body. The optimum condition for movement is realised by a smooth sphere, which reduces friction to a minimum. On the other hand, a rough surface resists movement. The moral is that the position of a foreign body should be verified at the time of operation and the patient placed in a position in which gravity opposes further movement.

SKIN DISEASES PRODUCED BY LUBRICANTS.

WE have received from the Department of Scientific and Industrial Research a copy of a Memorandum on "Cutting Lubricants and Cooling Liquids and on Skin Diseases Produced by Lubricants." It is explained that cutting lubricants and cooling liquids are oils or emulsions used in connexion with the cutting of metal. In selecting the correct grade of cutting lubricants it would appear to be necessary to consider several important factors, such as (1) cutting speed and depth of cut; (2) the material under manufacture; (3) the system of application of the lubricant or emulsion; and (4) the production of skin diseases. Particulars as to the suitability of various oils and emulsions and their adaptability on the various metal materials used are given under the first three heads and are of technical importance. Passing over these, we deal with the medical aspects of this occupation. Generally speaking, it appears from the description given by Dr. J. C. Bridge, Inspector of Factories, Home Office, that oil rashes are of two kinds—the first is due to plugging of the small glands at the root of the hairs on the arms and legs of the workers, the second to mechanical injury to the skin produced by metallic particles suspended in the cutting lubricant. In the first case, if many hairs are affected the arm or leg presents an appearance of a crop of raised red spots (papules) with a black spot as a centre, or if the inflammation has gone as far as suppuration (abscess formation) a yellow head. In the second case minute particles suspended in the cutting lubricant may produce injury to the skin. This occurs chiefly on the hands, where two skin surfaces are rubbed together, as, for example, between the fingers. Injury to the skin may also be produced on any part of the hands and arms by wiping with a cloth or rag while the hands or arms are coated with a film of fluid in which metallic particles are suspended. A septic infection may result. Simple precautionary measures are suggested, such as a free use of hot water, soap, and the scrubbing brush, and dusting the arms before commencing work with a powder containing equal parts of starch and zinc oxide. Constant removal of metal particles is necessary to avoid injury to the skin. The oils should not contain free fatty acid. In the case of cutting oils which get thinner on heating the metal particles will sink completely out. The addition of disinfectants or antiseptics to the oils does not appear to give satisfactory results, although a previous heating of the oil not only sterilises it but increases its antiseptic and germicidal action. As to treatment, the simple application of a mild antiseptic gives good results. It is curious that certain individuals appear to be particularly susceptible to the action of lubricants, and are therefore best kept from contact with the oil.

IMPRISONMENT FOR MILK ADULTERATION.

AT Folkestone recently a dairyman named Percy Jell was sentenced to undergo two terms of three months' imprisonment with hard labour for adulterating milk. A pint of milk sold by him to an inspector had been found to contain 43 per cent. of added water, and two days after this sale took place he had been seen pouring half a gallon of yellowish water into a two-gallon can which was then filled with milk from a churn. The yellow colour referred to was, no doubt, used in order to give to the compound sold the tint which the general public associate with richness in milk, and to avoid the bluish tint which at one time earned for milk in the metropolis the name of "London blue." It is to be presumed that the two terms of imprisonment awarded will have to be served consecutively and not concurrently, and no one will deny that he has been over punished. He would have richly deserved his sentences if the offences described had stood alone. It was, however, stated that during the current year Jell had paid fines amounting to more than £100 in respect of convictions for adulterating milk. He must have been able, therefore, to conduct a fairly prosperous trade in watered milk in spite of the fact that his dishonest propensities were well known to the authorities. To this it may be added that on leaving prison there is nothing, so far as we are aware, to prevent Jell from again carrying on business as a milk-dealer, which suggests that the issue of licences to dairymen as they are issued to hackney carriage drivers might be a practicable way of protecting the food of the people. Forfeiture of a licence with severe penalties for obtaining one without being entitled to it, or for selling milk as a business if not duly licensed, would be a more effective penalty than an inadequate fine or even than hard labour.

THE Harveian Oration will be delivered by Dr. Percy Kidd, at the Royal College of Physicians of London, on Friday, Oct. 18th, at 4 P.M.

A VALUED collaborator in our editorial work over a range of not less than 50 years, Mr. Robert Brudenell Carter, consulting ophthalmic surgeon to St. George's Hospital, London, has this week attained his ninetieth birthday.

WE regret to announce the death of Dr. Alfred Hume Griffith, the value of whose work as superintendent of the Epileptic Colony at Lingfield has earned wide recognition.

MEDICAL MEN IN PARLIAMENT.

A MEETING of the medical profession was held in Steinway Hall, London, on Oct. 1st, having for its object the securing of a more adequate representation of the medical profession in Parliament. The meeting was summoned informally and was well attended, all parts of Steinway Hall being crowded.

Sir HENRY MORRIS, who presided, opened the proceedings by emphasising the fact that after the war the medical profession would share in the great changes that would occur in all society. The organisers of the meeting, he said, had no desire to oppose any union, association, or committee, working along similar lines, and no intention of impeding any individual doctor who wished to become a Member of Parliament. The real object of the meeting, if the medical voice was considered to be needful in Parliament, was the choice of an executive upon whom the onus would be put of selecting suitable members of the medical profession who were willing to stand as Parliamentary candidates. Regarding this country as having originated all the great discoveries in public health and sanitation, he said that it was an anomaly that the medical profession should have no more influential voice in the legislature than at present it possessed. The idea of those responsible for the meeting was to elect an executive committee, independently of any section or fund, such committee to seek out and select suitable members of the profession who would be willing to stand for Parliament and to see that such men were representative of the profession as a whole. It would be important to have the candidates in readiness. The subjects on which such Members could give valuable help were very numerous, but he directed special attention to medical research and education and the application of scientific knowledge to the betterment of the community. Research must receive State aid; it could no longer be self-supporting if it was to be adequate. He asked whether the House of Commons as at present constituted could be regarded as an assembly to decide such questions as he had referred to, composed chiefly, as it was, of lawyers, landlords, mine-owners, ship-owners, and successful business men, with only a few educationists. As an instance, there were the questions as to whether, and if so how, laboratories might be bound up with the Universities, medical schools, special and general hospitals, or health insurance committees, and questions as to the scientific investigations, regular and special, which were undertaken from time to time on the authority of the various Government Departments or Royal Commissions. It was high time that the profession should take steps to show its importance to the State and to the public through the voice of competent and reliable members of the profession. A candidate for this representation should possess learning, knowledge, humanity, and probity; he ought also to be acquainted with some form of official life, and be able to express his views clearly and forcibly in public. In addition he should possess expert knowledge, so that he could apply his knowledge of medicine and surgery to the various problems connected with the public health and medical education. He should impress people with the fact that while defending his profession he intended to act strictly for the public good. They did not want men who would hug delusions as if they were principles, or fads as if they were ideals, or who would take part in political intrigues under the impression that they were democratic reforms. Numerically the medical profession was very weak for electioneering purposes. Members of the profession were unlike those of the Labour Party, who could present overwhelming numbers in any constituency so as to make their election secure; nor were they like lawyers, to whom speaking at political meetings was a good training for their profession. Medical men were feeble folk, coneys who made their houses in the rock of private practice; they were the confidants and friends of private families, who were likely to mistrust a doctor who concerned himself with the matters of communal welfare. Hitherto the profession had had no political standing in this country, and that state of things could not last. There should be means of getting the best brains of the profession without electioneering, such as by direct representation, as in the case of the Universities, or through the various medical corporations.

Dr. CHRISTOPHER ADDISON, Minister of Reconstruction, then moved the first resolution in the following terms:—

That in the interest of the national health it is essential that the considered views of the medical profession should be voiced by representative medical men in the House of Commons.

He said that after the war, with the upheavals, displacements, reactions, and burdens of loss and debt, there must be a vital need that the best service should be supplied to the State by all persons, or civilisation would be in jeopardy. A brief consideration of the facts of our national and social life would, he thought, reveal a wealth of opportunity for advice, direction, and help from all medical men of the right type and training in matters affecting the health of the people, such as the conditions of labour, the methods of production, and the processes of invention and research; in all these classes of public affairs men possessing medical knowledge should be invaluable. Pointing out that no medical man could be a politician in respect of disease, he did not consider that this meant that, as a citizen, he should not take the keenest interest in political affairs, and he reminded the audience that a medical man in Parliament would be there as a representative of his constituency, that is of the people, and not as a medical man. In Parliament any Member who tried to promote the best public interest could, he assured them, safely place professional interests second in his mind and escape the depressing career of the professional axe-grinder. Premising that the House of Commons "is a most tolerant and kindly place, putting sincerity and earnestness of purpose, if coupled with common sense, in the forefront of its regard," he said that medical help would be more and more required in the counsels of the nation, while he held that the claims for representation in Parliament by medical men were supported by medical activities during the war, as shown by the combating of new and vile methods of warfare introduced by the Germans, the rapid improvement in the methods of surgery, the developments for the training and employment of the wounded, and the institution of scientific research in manifold directions. Especially he called attention to the great success of medicine in the preventive field, whereby, for example, typhoid fever had been nearly abolished, a fever which, in a war of hideous magnitude lasting for so long a period, might well have cost the country a million lives. Quoting the Prime Minister, he said we could not run an A1 Class nation on a C3 Class population, which was only to insist that all questions affecting the home, workshop, school, personal habits, food, air, and exercise require the profound attention of Parliament, and therefore the help of medical men. He alluded to the report of the Health of Munition Workers Committee, a body set up by Mr. Lloyd George and himself when they were collaborators at the Ministry of Munitions, and showed that as far as it went this report contained valuable guidance. In February, 1914, to a company of medical men, he had referred to these things, and pointed out that as a first step it was necessary to bring together the assortment of different departmental responsibilities in health matters and to secure that the thinking out and development of a systematic health policy commensurate with the most urgent national needs should be made the duty and responsibility of a definite body of men, until when the country would be the victim of sporadic, disjointed, and often conflicting effort. Throughout the progress of the war, he said, it had become more and more apparent that delay was dangerous, so that during 1917, at the request of Mr. Montagu and the late Lord Rhondda, whose clear mind in this as in other things at once gripped essentials, he had presided over a small committee which presented a report on what was regarded as the absolute minimum of such a scheme—a scheme for a Health Ministry. During the past few months as Minister of Reconstruction he had discussed details with representative bodies of different kinds, including representatives of a joint committee provided by the Colleges of Surgeons and Physicians and the Society of Medical Officers of Health, as well as with a committee of the British Medical Association. Now, he informed his hearers, the proposals had been examined as a whole and with great care by the Home Affairs Committee, and had been passed by them to the War Cabinet for consideration. The Ministry of Health would not itself be a health service. It would be its duty to secure the development and administration throughout the country of adequate health services. He concluded by pointing out

that the C 3 Class, and all implied by that term, could not be dealt with as matters of water-supply, drainage, prevention of infective disease, or adulteration of food, and that the medical profession had a great duty and an unexampled opportunity before it. The claims of the community for the considered experience and help of medical men were, he said, manifest.

Dr. ARTHUR LATHAM, in seconding the motion, asked whether medical men realised that they were the trustees of the national health, and that no one could take their place. If they were prepared to accept the responsibilities and duties of that proud office, they must be prepared to learn from the mistakes of the past. In the past the profession had not made its voice heard because it had no political power, and the latter was lacking because the profession was not united. It was especially important that the knowledge and experience of the general practitioner should be represented.

Mr. E. B. TURNER emphasised the resolution from his large experience in addressing meetings throughout the country in regard to venereal disease.

Sir W. WATSON CHEYNE remarked that there would not be enough medical men in the House to impress it by numbers; it must be by exactly informed judicial utterances. Above all was it necessary that there should not be divided counsels, as any good effect would thereby be destroyed. He hoped that there would be a little medical gathering of Members of Parliament and that they would agree on lines of policy in matters which concerned the profession.

Colonel KYNASTON spoke of his work in the Army Medical Service and the great need there was for enlightenment on medical and public health matters in the constituencies. The scheme now sought to be launched should be on a democratic basis.

The resolution was agreed to.

Mr. E. F. WHITE moved :—

That a Representative Committee be appointed for the purpose of: (i.) Nominating medical men as being suitable to voice the opinion of the profession in the House of Commons on matters affecting the national health; (ii.) taking such steps as may be possible to further the election of those nominated to the House of Commons; and that this committee report to a subsequent general meeting of the profession.

Mr. LOCKHART MUMMERY seconded.

Colonel KYNASTON proposed, and it was duly seconded, an amendment as follows :—

That a Representative Committee be appointed for the purpose of taking such steps as may be possible to further the election of medical men to the House of Commons.

Dr. BRACKENBURY pointed out the great need for unity in this matter, and referred to a committee which had already been in existence six months with the same object.

In a discussion which followed.

Colonel W. R. SMITH objected to the motion, and said he would be satisfied if it were put without Section 1.

Colonel Kynaston's amendment was, by leave, withdrawn in favour of Colonel Smith's.

Mr. N. BISHOP HARMAN protested against this attempt to step in when 23,000 members of the British Medical Association had instructed their duly accredited representatives, who had been working at the matter during the last six months.

The amendment was agreed to, and was passed as a substantive motion.

Sir THOMAS HORDER moved :—

That the Representative Committee consist of: (i.) a representative of each of the following ten organisations or corporations—(1) Royal College of Physicians, (2) Royal College of Surgeons, (3) Royal Society of Medicine, (4) British Medical Association, (5) Incorporated Society of Medical Officers of Health, (6) Medical Society of London, (7) Medical Political Union, (8) Medical Women's Federation, (9) Poor-Law Medical Officers' Association, (10) State Medical Service Association; (ii.) three representatives of the Medical Press—namely, the Editor of *The Lancet*, the Editor of the *British Medical Journal*, the Editor of the *Medical World*; (iii.) unofficial members.

Dr. E. H. M. STANCOMB (Southampton) seconded. The result was a decision to appoint the Committee and to add the Royal Institute of Public Health and the R.A.M.C.

Considerable discussion ensued on a proviso on the voting paper supplied to the meeting that "persons who do not hand in voting papers will be counted as having voted for the list (of unofficial members) as printed." Dr. CHAPPLE, M.P., regarded such a provision as monstrous.

The CHAIRMAN having agreed to withdraw this, ballot papers were collected, and a vote of thanks to the Chairman and Dr. Addison concluded a long meeting.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Health of Belfast: Serious Condition.

IN the *Belfast Northern Whig* some most alarming figures have been recently published as regards the health of the city of Belfast. In 1917 there were 932 deaths from pulmonary phthisis, as against 830 in 1916 and 813 in 1915. Notwithstanding the fact that a new scheme for dealing with tuberculosis (specially praised by the Irish Local Government Board) has been in vogue for the past two years, costing £35,000 a year, it appears that from Dec. 20th, 1917, to August 20th, 1918, the number of deaths registered in Belfast as caused by pulmonary phthisis was 783, as against 711 in the same period of 1916–17, which is an increase of 72, or 10·1 per cent., and the phthisis rate for 1918 was actually 2·4 per 1000, which is higher than for any year since 1907. Bad as these tuberculosis figures are, what is to be said for the infantile mortality rate, which is generally admitted to be the test of effective public health measures? In 1917 the rate rose to 130 per 1000 births, an increase of 17 per 1000 as compared with the preceding year. The actual number of deaths of children under 1 year in 1917 was 1130. Now, in the eight months (between Dec. 20th, 1917, and August 20th, 1918) the deaths of children under 1 year numbered 936, as against 808 in the same period of the previous year, an increase of 128, or 15·8 per cent. In the first six months of the period (for some reason not specified no figures were published for the last two months) the deaths of children of 1 year and under 5 years were 599, as against 378 in the corresponding period of last year. And taking the six months—Dec. 20th, 1917, to June, 1918—there died of children under 5 years old in the city 1313, out of a total death-rate of 3999. Thus roughly one-third of the entire city death-roll in that period consisted of children under 5 years old! This state of affairs was before the influenza epidemic of this year reached its climax. In the five weeks, June 18th to July 25th, no fewer than 1232 persons died (influenza period), but, as showing that influenza was not a factor in the infantile mortality, only 133 children under 1 year died in these five weeks, whereas in the same period in April–May, they totalled 172, and in February–March, 140. What is a most serious circumstance is that during that period of six months specified there were only 4666 births as against 3999 deaths—that is, a natural increase of only 665. During the past eight months (mid-December to mid-August) the total deaths in Belfast were 5695 as against 4993 in the corresponding period of the previous year, and the total births 6346 as against 6097 in the corresponding period. In other words, the deaths increased by 702 (14 per cent.) and the births by 249 (3·9 per cent.), a most unfortunate state of affairs, as regards the natural increase of Belfast's population. The new child welfare scheme (which has neither ante-natal nor post-natal clinics, creches nor milk depôts) came into vogue in October, 1917; but so far as diminishing infantile mortality is concerned, it has really done nothing, though—like the tuberculosis scheme—it is costing a great deal of money. Owing to its present limited field of organisation, little can be hoped from it. The following figures are most significant as regards Belfast :—

	Total deaths.		Under 1 year.		1 year and under 5.	
	1918.	1917.	1918.	1917.	1918.	1917.
Dec.–Jan.	720	779	122	99	83	42
Feb.	594	829	99	175	92	93
March	654	751	140	144	111	79
April	940	821	172	133	166	71

Salaries of Dispensary Doctors.

At a meeting of the Banbridge guardians, held on Sept. 9th, it was decided that a war bonus of £25 a year be granted to each medical officer, to date from Jan. 1st, 1918, a motion for a graded scale of payment, commencing with £130 and ending with £200 a year, being lost. The Omagh dispensary doctors decided on Sept. 11th that notice be given the guardians that from the 21st the doctors will be reluctantly compelled to cease all kinds of dispensary work

owing to no attempt having been made to meet their demands. On the day named the guardians met and appointed their chairman to confer with a member of the Medical Committee and Mr. E. F. Stephenson, of the Local Government Board, with a view of arriving at a settlement. The doctors were invited to continue work until the guardians had had an opportunity of discussing the finding of this conference.

Sept. 30th.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Canadian Voluntary War Contributions.

OF the various war organisations working in Canada and overseas the most extensive are the Canadian Patriotic Fund for dependents of soldiers, the Canadian Red Cross Society, and the Military Branch of the Y.M.C.A. The first-named has raised about $40,000,000 (£8,218,600) throughout the Dominion; and Manitoba, working alone, nearly $4,000,000. The Canadian Red Cross in money and gifts has received about $19,000,000; the British Red Cross Society, to Dec. 31st, 1917, $6,100,000; Belgian relief, over $3,000,000; Military Branch, Y.M.C.A., about $4,600,000; gifts from Dominion and Provincial Governments to Imperial Government, about $5,500,000; and miscellaneous equipment and maintenance of hospitals overseas, field comforts, Polish and Serbian and French Relief Funds, about $8,000,000—making a grand total of over $90,000,000 (£18,491,850), which will still be added to by several millions for the mercantile marine.

Canadian Pensions.

In October, 1917, the Canadian Government brought into effect a scale of pensions which is believed to compare favourably with any of the Allies: Total disability, $600; widows, $480; parents, $480; children, $96; orphan children, $192; special allowance for helplessness, not to exceed $300—number of classes of disability, 20; and gratuity. To the end of May, 1918, the number of soldiers' disabilities have totalled 23,415, and the amount of annual liabilities, $3,687,145.61; soldiers' dependents, 24,213, and the annual liability, $5,600,326.00. The estimated liability for the year ending March 31st, 1919, is $15,000,000 (£3,081,975). Pensions in Canada are now being awarded at the rate of 125 per day, and 22 physicians, most of them having seen overseas service, are employed by the Pension Board at Ottawa. The salary for these was at the rate of $200 per month, but recently raised to $250 per month.

Casualties in the Canadian Expeditionary Force.

Up to June 30th, 1918, the official statement of the Canadian Government of the Canadian casualties gives the total number as 159,084, divided as follows: killed in action, 27,040; died of wounds, 9280; wounded, 113,007; died of disease, 2257; prisoners of war, 2774; presumed dead, 4342; missing, 384. Of the wounded and sick, between 30,000 and 40,000 have been returned to France for further service; about 50,000 have been returned to Canada wounded, medically unfit, or unavailable for various reasons. Some 200 Canadian officers have been lent to the United States for instructional purposes. About 2000 women have enlisted in Canada for services as nurses in the C.E.F. Seventy-three surgeon-probationers have been recruited in Canada for service with the Royal Navy.

Resolutions Passed at Hamilton Medical Meeting.

The following resolutions were passed at the Canadian Medical Week at Hamilton recently:—

1. That the various Provincial Medical Councils of Canada be respectfully requested to institute compulsory examinations in ophthalmology, including refraction work, and in oto-laryngology, if such are not already in force.
2. That the medical faculties of the universities in Canada be respectfully requested to confer, and, as far as possible, coöperate with a view to modifying the present curriculum so as to secure an arrangement of the subjects of study which will tend to ensure a more symmetrical training of the prospective practitioner for his life work.
3. That the various provincial medical councils be respectfully requested to make physical therapy, based on a more thorough course in physics, an essential feature of the medical curriculum, and a practical examination necessary in this subdepartment of therapeutics.
4. That the members of the Canadian Medical Association view with favour the publication of the medical history of the Halifax disaster by Professor D. Fraser Harris, of Halifax, and wish to state that in their opinion such a publication is most desirable.

The Khaki University of Canada.

Under the name of the Khaki University of Canada an educational plan has been inaugurated with the Canadian Forces overseas. It provides educational advantages in the form of lectures, study groups, &c., for soldiers who wish to use their spare time for practical study for after-war vocations. This Khaki University is recognised by Canadian universities, and the teaching is done by voluntary instructors—officers, chaplains, &c., who had previously had training in teaching. Sir Robert Falconer, President of the University of Toronto, is at present overseas, doing his bit as a teacher. There are said to be 93 libraries established in England and France, and that 8006 men have been registered, divided as to subjects as follows: commercial subjects, 2351; agricultural subjects, 1363; engineering, 1503; general educational subjects, 2789. Figures are not yet available as to classes in France.

Toronto, Sept. 21st.

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

SUBSCRIPTIONS TO THE SECOND APPEAL.

THE following subscriptions, completing the list up to Monday, Sept. 23rd, should have been acknowledged in our previous issue:—

	£	s.	d.		£	s.	d.
Sir A. Pearce Gould ...	5	0	0	Major W. M. A. Fletcher	1	1	0
Messrs. Bower and Sons	2	2	0	Dr. F. G. Clemow	5	0	0
Capt. A. Benjamin ...	1	1	0	Dr. S. H. Bown	1	1	0
Dr. Norman Fairfax ...	1	1	0	Dr. H. Leader	2	2	0
Dr. A. W. Cassie	1	1	0	Mr. A. Williams, M.P.S.	1	1	0

Monthly Subscriptions.

The following monthly subscriptions have been received for September:—

	£	s.	d.		£	s.	d.
Sir A. Pearce Gould ...	5	5	0	Dr. G. Grey Turner ...	1	1	0
Mr. E. Spencer Evans ...	0	10	0	Dr. W. S. Hart	1	0	0
Dr. Alfred Cox	1	1	0	Dr. Vincent Tighe	0	10	0
Dr. A. B. Stevens	1	0	0	Lt. J. B. C. Brockwell,			
Dr. E. C. Morland	0	10	6	R.A.M.C.	0	10	0
Dr. K. J. Dougall	0	10	0	Dr. A. W. Forrest	1	0	0
Sir T. Barlow	0	10	0	Dr. W. Luffman	0	10	0
Dr. R. Legat	0	10	6	Dr. A. Graham	1	1	0
Dr. A. E. Naish	0	10	0	Dr. A. Hawkyard	0	10	0
Dr. Hyla Greeves	0	10	0	Surg. P. G. S. Davis,			
Dr. W. E. Good	0	10	0	R.N.	0	10	0
Major E. R. Fothergill,				Dr. H. Caiger	0	10	6
R.A.M.C.	0	10	0	Capt. H. L. P. Hultert,			
Dr. J. O. Musson	0	10	0	R.A.M.C.	1	0	0
Dr. W. Stewart	0	10	0	Dr. H. Whitehouse ...	0	10	0

Subscriptions to the Fund should be sent to the treasurer of the Fund, Dr. H. A. Des Vœux, at 14, Buckingham Gate, London, S.W. 1, and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

URBAN VITAL STATISTICS.

(Week ended Sept. 28th, 1918.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality was 11·4, against 11·3 and 11·7 per 1000 in the two preceding weeks. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 12·2, or 0·4 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 4·9 in Ealing, 5·0 in Cambridge, and 5·2 in Darlington, to 19·0 in Dudley, 19·5 in Great Yarmouth, and 20·5 in Hastings. The principal epidemic diseases caused 307 deaths, which corresponded to an annual rate of 1·0 per 1000, and included 220 from infantile diarrhœa, 40 from diphtheria, 20 from whooping-cough, 12 from measles, 8 from scarlet fever, and 7 from enteric fever. The deaths from diarrhœa, which had declined from 435 to 299 in the four preceding weeks, further fell to 220, and included 67 in London, 24 in Liverpool, 10 in Sheffield, and 8 each in Birmingham and Middlesbrough. The 939 cases of scarlet fever and 1060 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 100 and 35 above the respective numbers remaining at the end of the previous week. Of the total deaths in the 96 towns 139 resulted from violence. The causes of 33 deaths were uncertified, and included 7 each in Birmingham and Liverpool, and 4 in Manchester.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,500,000 persons, the annual rate of mortality was 14·3, against 10·6 and 11·6 per 1000 in the two preceding weeks. The 398 deaths in Glasgow corresponded to an annual rate of 18·6 per 1000, and included 12 from infantile diarrhœa, 7 from diphtheria, 5 from whooping-cough, and 2 from measles. The 76 deaths in Edinburgh were equal to a rate of 11·9 per 1000, and included 2 from diphtheria and 2 from infantile diarrhœa.

Irish Towns.—The 153 deaths in Dublin corresponded to an annual rate of 20·0, or 3·1 per 1000 above that recorded in the previous week, and included 6 from infantile diarrhœa, 2 from whooping-cough, and 1 from enteric fever. The 77 deaths in Belfast were equal to a rate of 10·2 per 1000, and included 3 from infantile diarrhœa and 1 from enteric fever.

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue :—

Killed.

Lieut.-Col. R. T. Collins, D.S.O., R.A.M.C., was a student at Guy's Hospital, London, and qualified in 1902. Shortly afterwards he joined the R.A.M.C. The award of the D.S.O. was recorded in THE LANCET of Jan. 12th, 1918, p. 78.

Capt. C. R. Howard, R.A.M.C., attached King's African Rifles, was educated at Cambridge University and at Guy's Hospital, London, and qualified in 1902. At the time of joining up he was in practice at Frome, Somerset, where he was M.O.H. to the rural district council, assistant school medical officer to the County Education Committee, and honorary surgeon to the Victoria Hospital.

Capt. C. H. Fischel, R.A.M.C., attached Leicester Regiment, qualified in London in 1914, and joined the R.A.M.C. in the early part of the following year.

Major H. B. German, M.C., R.A.M.C., was a student at Guy's Hospital, and qualified in 1904. For some years he served in the Royal Navy, and was awarded a medal for services in connexion with the Calabrian earthquake. Later he practised at Waltham Abbey, Essex, and joined the R.A.M.C. soon after the outbreak of war.

Died of Wounds.

Major J. Hughston, R.A.M.C.

Previously Reported Wounded, now Reported Died of Wounds.

Capt. L. E. W. Roberts, Australian A.M.C.

Died.

Lieut. L. S. Ramien, I.M.S., was educated at Madras University, and qualified in London in 1916, joining the I.M.S. shortly afterwards.

Capt. T. F. Graham, Canadian A.M.C. (See Obituary of the War.)

Wounded.

Capt. G. R. Phillips, R.A.M.C., attached Sherwood Foresters.
Surg. R. K. Shaw, R.N.
Lieut.-Col. K. W. MacKenzie, D.S.O., M.C., R.A.M.C.
Capt. J. McCusker, Australian A.M.C.
Capt. K. McLean, Australian A.M.C.
Capt. J. H. Campain, R.A.M.C., attached Wilts Regiment.
Lieut. G. E. Birkett, R.A.M.C., attached Glos. Regiment.
Major W. Russell, M.C., R.A.M.C.
Major E. S. Sowerby, M.C., R.A.M.C.
Capt. K. McA. Ross, R.A.M.C., attached Highland L.I.
Capt. W. K. Flook, Australian A.M.C.

Seriously Injured.

Acting Staff Surg. E. L. Atkinson, D.S.O., R.N.

Missing.

Capt. J. Buchanan, R.A.M.C., attd. Roy. Warwickshire Regt.

THE HONOURS LIST.

The following awards to medical officers are gazetted. All are members of the R.A.M.C. except where otherwise stated :—

Distinguished Service Order.

Major (temp. Lieut.-Col.) ALBERT RICHARD HENCHLEY.—For conspicuous gallantry and devotion to duty during an enemy attack. In two days he succeeded in evacuating some 1500 patients. He got away his personnel and lorries under shell and machine-gun fire, and proceeded to a hospital elsewhere from which he evacuated 300 wounded by ambulance trains. His unit was the last to leave the town. His coolness and resource were the means of saving a large number of wounded from falling into the hands of the enemy.

Bar to the Military Cross.

Capt. (acting Major) ROGER ERRINGTON, M.C.—For conspicuous gallantry and devotion to duty during an enemy attack. He remained in his dressing station under machine-gun fire until it was evacuated. He then took another dressing station and again under machine-gun fire evacuated all patients. It was entirely due to his coolness and devotion to duty that these wounded did not fall into the hands of the enemy.

Temp. Capt. PAUL MACDONALD LITTLE, M.C.—For conspicuous gallantry and devotion to duty in attending to wounded in the front line under heavy shell, machine-gun, and rifle fire. His example of coolness and devotion to duty caused a large number of wounded to be successfully evacuated from the front line.

Temp. Capt. ALAN COWAN MANN, M.C.—For conspicuous gallantry and devotion to duty during an enemy attack. Hearing that a number of wounded had been left in a dressing station, he organised bearer parties and led them through heavy shell fire to the dressing station and evacuated all the wounded. Through his devotion to duty many wounded were cleared who would otherwise have been abandoned.

Capt. (acting Major) ROBERT TAYLOR, M.C.—For conspicuous gallantry and devotion to duty while in command of an advanced dressing station. He worked with untiring energy, attending to and supervising the loading on to cars of all cases. The dressing station was hit several times, and eventually came under machine-gun fire, but he succeeded in clearing all wounded. He showed fine determination and devotion to duty.

Military Cross.

Capt. ALFRED LANG BODLEY.—For conspicuous gallantry and devotion to duty. When a dug-out was heavily shelled and blown in he rescued a man from the most dangerous place where three men lay buried, and attended to the men affected, assisting to get them away. In one case he tried for hours to save a man who had lost consciousness, and during this time lost consciousness himself, but continued his work on recovering. His personal example of courage was of the utmost assistance.

Capt. JAMES IVER MCIVER CHIRNSIDE, Australian A.M.C.—For conspicuous gallantry and devotion to duty while attending to wounded men under heavy shell and machine-gun fire. During the retirement of the rearguard squadron he attended to the wounded while the enemy were firing at a distance of 300 yards. He showed great devotion to duty.

Temp. Capt. WILLIAM COOPER.—For conspicuous gallantry and devotion to duty during an enemy attack. He was unremitting in his attentions to wounded under fire, and stayed behind in a village with a small salvage party attending to a number of wounded and gassed officers and men who came in. He behaved splendidly.

Temp. Capt. GUY DE HOGHTON DAWSON.—For conspicuous gallantry and devotion to duty. During an arduous period of retirement, lasting for some days, he worked with unflagging energy in attending to the wounded under heavy fire, evacuating them successfully, on one occasion when the enemy were within 40 yards of the R.A.P. His example helped and encouraged all those under his command.

Capt. CHRISTOPHER MATHESON FINLAYSON, Canadian A.M.C.—For conspicuous gallantry and devotion to duty. During a raid on the enemy's positions he worked at the advanced aid-post with the greatest gallantry and unselfish courage. Later he withdrew to the fixed rear aid-post and performed valuable duties.

Capt. (acting Major) ROBERT ALFRED GREENWOOD.—For conspicuous gallantry and devotion to duty in evacuating the wounded. When a bridge was blocked and partly submerged by a fallen tree he supervised the clearing and helped to carry the wounded across under heavy shell fire on both banks. Though severely shaken by a shell bursting and partially burying him, he carried on until all the wounded were safely across the canal.

Temp Capt. NORMAN MCALISTER GREGG.—For conspicuous gallantry and devotion to duty during a raid. He untiringly attended to the wounded under heavy enemy fire until the last man was cleared, and showed great coolness and devotion to duty. He worked persistently throughout the raid in the open, and searched for any wounded that might have been overlooked. He behaved splendidly.

Capt. HENRY TAYLOR LAMB.—For conspicuous gallantry and devotion to duty when an outpost company were suffering numerous casualties from enemy bombardment. He proceeded to the locality at once, and under heavy shelling got all the wounded moved to shelter, remaining with the company until the bombardment ceased. During a trying time he showed splendid devotion to duty.

Temp. Capt. WILLIAM LUMSDEN.—For conspicuous gallantry and devotion to duty. While in charge of bearers carrying wounded over an exposed hill-side swept by shell and machine-gun fire he saw a bearer fall. He at once ran to him and dressed his wounds, after which he remained with him until dusk, the man being unable to walk. He then assisted him across country to a place of safety. His conduct was splendid.

Capt. JOHN ERIC MCGLASHAN, Australian A.M.C.—For conspicuous gallantry and devotion to duty in charge of the evacuation of wounded during an attack. He visited his various posts under heavy shell and machine-gun fire and was largely responsible for the successful evacuation of the wounded.

Capt. (acting Major) KENNETH ARLY PORTERFIELD RYND MURRAY.—For conspicuous gallantry and devotion to duty in charge of an advanced dressing station during an enemy attack. He worked continuously for two days, often under heavy shell fire, and evacuated over 200 cases. Owing to the constant change of position he had great difficulty in keeping touch with the medical officers of the regiments he was clearing, and only succeeded in doing so by visiting them all personally on several occasions. His courage and magnificent devotion to duty set a fine example to all his men.

Temp. Lieut. THOMAS GORDON PLAYFORD.—For conspicuous gallantry and devotion to duty. Assisted by an orderly, he dressed the wounds of several officers on the roadside under heavy shell fire. Later, he established a dressing station in a village which was rapidly being enveloped by the enemy, and succeeded in clearing all his casualties before it was evacuated.

Lieut. (acting Major) RAYMOND STOWERS.—For conspicuous gallantry and devotion to duty in command of an advanced dressing station subjected for hours to heavy shelling. He got all cases away in a most expeditious manner. Subsequently, on the near approach of the enemy, he got his personnel and cars away and opened a temporary dressing station elsewhere, and continued to evacuate wounded till ordered to retire. He showed fine devotion to duty.

Capt. HUGH COMPSON TRUMBLE, Australian A.M.C.—For conspicuous gallantry and devotion to duty. Under heavy enemy barrage he pushed forward some 600 yards with his medical personnel to a ledge, where by his capable organisation he successfully evacuated quantities of wounded. He worked for three days and nights, and his quiet courage had an excellent effect on wounded and stretcher-bearers alike.

Capt. CECIL MCLAREN WEST.—For conspicuous gallantry and devotion to duty. On three occasions he went through heavy shell fire to attend casualties in batteries which were under fire, the roads all the time being heavily shelled with high explosives, shrapnel, and gas shells.

Capt. (acting Major) MAURICE ULICK WILSON.—For conspicuous gallantry and devotion to duty during an attack. He continually attended wounded at the advanced dressing station, which was constantly under artillery fire (four shells dropped within a few yards of the operating table). The work was continued without cessation, so that 247 cases were evacuated in 38 hours. He showed fine devotion to duty under very difficult circumstances.

OBITUARY OF THE WAR.

KINGSMILL WILLIAMS JONES, M.D., D.P.H. DUB.,

DISTINGUISHED SERVICE ORDER,
CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain K. W. Jones, who was killed in action in Flanders on August 2nd, aged 43 years, was son of the late Percival Jones of Dublin. He was educated at Wesley College and Trinity College, Dublin, where he obtained a mathematical scholarship. He graduated B.A. in 1898, M.B., B.Ch., B.A.O. in 1901, M.A., M.D., and D.P.H. in 1903. After holding some resident appointments he started in private practice in Manchester, where he rapidly created a successful position for himself. Captain Jones was a keen Territorial, and proceeded with his unit, the 18th Field Ambulance, to France in September, 1914, and shortly afterwards became attached as M.O. to the 1st Buffs, with which battalion he was serving at the time of his death. In August, 1915, Captain Jones was wounded at Hooge, and for his gallantry and devotion to duty under fire on that occasion was awarded the D.S.O. In September, 1916, he was very severely wounded at the battle of the Somme, but returned to France again in February, 1917. He rejoined the 1st Buffs in January, 1918, and was badly gassed in May, but returned to his regiment and was killed in action on August 2nd. He refused promotion on more than one occasion in order to remain with his regiment. A colleague who was in intimate association with Captain Jones for many years writes of him :—"In his relationships both with his patients and his medical colleagues he was justly regarded with the highest esteem for professional ability, high standards, and unfailing sympathy with those in trouble. To his friends the sense of loss is very real, for he was a charitable, humorous, and hospitable man, and a 'gentleman unafraid.'"

WILLIAM MARGETSON HEALD, M.R.C.S. ENG.,

LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant W. M. Heald, who died at the Red Cross Hospital, Rouen, on Sept. 8th, aged 24, from wounds received in his aid-post on the Somme on August 22nd, was the only son of the Rev. C. W. Heald, of Chale Rectory, Isle of Wight. He was educated at Marlborough and gained an exhibition at St. John's College, Cambridge, where he graduated B.A. in 1916. He took his M.R.C.S. and L.R.C.P. from St. Bartholomew's Hospital, London, in January, 1918, and held the appointment of junior house physician there till April 7th, when he received his commission in the R.A.M.C. After ten days at Blackpool he sailed for France, where he was attached to a Field Ambulance until a few weeks before his death, when he was appointed M.O. to the Lancashire Fusiliers. His commanding officer writes of Lieutenant Heald as an officer keen and reliable in his work, whose death will be a great loss to his regiment.

WILLIAM MORRIS LANSDALE, M.B., B.S. LOND.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain W. M. Lansdale, who was killed in action in France on August 26th, at the age of 27, was the eldest son of Dr. William Lansdale, of Grove Park, Lee, Kent. He was, as a schoolboy, an accomplished gymnast and swimmer. He entered Guy's Hospital in October, 1909, winning the entrance scholarship in Arts. In 1911 he gained the first proficiency prize and the Wooldridge Memorial prize in Physiology; in 1914 he won the Beaney prize in Pathology, and in the session 1913–14 he was the prize essayist of the Physical Society of Guy's Hospital. He was also one of the presidents of that society. He graduated M.B. and B.S. at the University of London in November, 1914, and at once joined the R.A.M.C. with the rank of lieutenant. A year later he was promoted to the rank of captain, and shortly after became M.O. in charge of the 107th Field Ambulance, with which he went to France in January, 1916. Later on he was for a short time attached as M.O. to a brigade of the R.F.A., and for the last year and a half was M.O. in charge 5th Royal Bucks Regiment. He was killed instantaneously by a shell shortly after telling some of his stretcher-bearers to take cover. The colonel of his regiment writes feelingly of the regard in which he was held by officers and men. A schoolfellow and colleague of Captain Lansdale notes the unassuming modesty with which he carried high academic distinction, and which added charm to his personality.

Captain THOMAS FLECK GRAHAM, C.A.M.C., who died suddenly of cardiac failure on Sept. 20th, at the age of 35 years, was son of Alexander Graham, of Brantford, Ontario. He was born at Guelph, Ont., graduated in medicine at the University of Toronto in 1914, and joined the C.A.M.C. in July, 1916. He served in the Hastings and Seaford districts until April of this year, when he went to France, attached to No. 3 Stationary Hospital. His special abilities led to his employment in resuscitation and wounds of chest cases, and the success he had with blood transfusion, which plays so important a part in the treatment of these cases, was a striking tribute to his skill.

Captain JAMES COTTON FORSYTH, C.A.M.C., who died of wounds at sea on Sept. 8th, aged 47 years, was a native of Mount Bridges. He graduated in medicine at the Western University, London, Ontario, in 1894, joined the C.A.M.C. in April, 1916, and after serving in England for a year was attached to No. 1 Canadian General Hospital in France. He was invalided to England in June, 1918, and died on the voyage back to Canada.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported :—

Lieut.-Col. R. T. Collins, D.S.O., R.A.M.C., killed in action, only son of Dr. E. W. Collins, late of Sydenham, Kent.

Second Lieut. R. L. Norton, Norfolk Regt., killed in action, only son of Dr. J. Norton, of Queen Anne's-gate, London, S.W.

H. Jakins, Queen's Westminster Rifles, died as prisoner of war in Germany, only son of Dr. P. Jakins, of Harley-street, London, W.

Lieut. C. G. Thomson, Somerset Light Infantry, killed in action, only son of Dr. E. B. Thomson, of Plymouth.

Capt. (acting Adjt.) H. G. Powers, M.C., Gurkhas, killed in action, only son of Dr. C. H. Powers, of Westend, Southampton.

Capt. R. H. Knight, Wiltshire Regiment, killed in action, younger son of Dr. A. A. H. Knight, of Lancaster.

THE WAR RECORD OF THE LONDON MEDICAL SCHOOLS: THE FOURTH YEAR OF WAR.

Our inquiry into the war record of the larger metropolitan medical schools has been continued throughout the fourth year of war. Figures for the second and third years were given in THE LANCET of Sept. 23rd, 1916, p. 579, and Sept. 22nd, 1917, p. 479, respectively. The supplementary figures which we now give must be taken as including all those of whom accurate information is available, but it is evidently impossible to keep the record entirely up to date. We may state again here that the deans of all the schools desire to be kept closely informed of the records of their men who are serving in the Navy and Army, and, we must now add, the Royal Air Force. Those schools which have furnished us with returns are given in alphabetical order:—

St. Bartholomew's.—From August 24th, 1917, to August 22nd, 1918, 100 joined the Army and 27 the Navy, making a total of 1918 for the four years. There were: Killed in action, 13; died from wounds, 5; died, 4; wounded, 38; gassed, 1; missing, 2; prisoners of war, 10; repatriated from Germany, 3; interned in Holland from Germany, 1; Mentioned in Despatches, 147. Distinctions: K.C.B., 2; K.C.M.G., 2; K.B.E., 1; C.B.E., 1; C.B., 4; C.M.G., 8; C.I.E., 2; O.B.E., 6; M.B.E., 1; D.S.O., 20; Military Cross, 39; Bar to Military Cross, 1. Promotion for Distinguished Services, 14; Knight of Grace of St. John of Jerusalem, 2; Associate of St. John of Jerusalem, 1; Order of St. Stanislas (3rd Class, with Swords), 1; Order of Kara George (4th Class, with Swords), 1; Cavalier of the Order of the Crown of Italy, 1; Order of Star of Roumania, 4th Class, 1; Order of St. Sava of Serbia (3rd Class), 1, (4th Class), 3; Serbian Red Cross Decoration, 1; Croix de Guerre avec Etoile d'Or, 1; Croix de Guerre, 2; Order of St. Anne, 3rd Class, 1; Albert Medal for saving life, 2; Bronze Medal for saving life at sea, 1; Order of the Nile, 3rd Class, 1; T.D. decoration, 2.

Charing Cross.—The number of past and present students on service, including members of the staff, as far as can be ascertained, is 306. Of these 9 have died on service. The following honours have been gained: K.C.B., 1; K.B.E., 1; Knight, 2; C.B., 2; C.M.G., 3; D.S.O., 5; M.C., 14. Order of St. Sava of Serbia: 2nd Class, 1; 4th Class, 2.

St. George's.—Of more than 400 men who are serving or have served in the present war, 7 have been killed in action, 1 has died of wounds, and 9 have died on active service. Two have been taken prisoner of war, one of whom, Major H. E. Priestley, C.M.G., has been since released. The following honours have been gained: K.C.B., 1; K.C.M.G., 2; C.B., 8; C.M.G., 8; D.S.O., 12; M.C., 18, and two Bars; D.S.C., 1; Order of St. Sava, 4; Croix de Guerre, 2.

King's College.—The completed figures are: Joined, 315; died, 19. Honours: K.C.B., 3; K.C.M.G., 4; K.C.V.O., 1; C.B., 6; C.M.G., 7; Military Cross, 15; Bar to D.S.O., 2; D.S.O., 15; Mentioned in Despatches, 51; Esquire of Order of St. John of Jerusalem, 1; Legion of Honour (Grand Officier), 1; Commandeur de l'Ordre de Léopold, 2; Croix de Guerre (Belgian), 1; Order of the Sacred Treasure (Japanese), 1; Order of St. Sava (Serbian), 1.

London Hospital Medical College.—The completed figures are: Joined, 1470; killed, 96. Honours: G.C.V.O., 1; K.C.B., 1; K.C.V.O., 2; K.B.E., 3; D.B.E., 1; Knighthood, 1; C.B., 5; C.M.G., 9; C.B.E., 3; Companions of Honour, 3; D.S.O., 32; D.S.C., 4; 2nd Bar to Military Cross, 2; Bar to Military Cross, 4; Military Cross, 112: Military Medal, 2; Order of St. John of Jerusalem, 4; Hon. Associates of the Order of St. John of Jerusalem, 2; Légion d'Honneur, Croix de Chevalier, 2; Croix de Guerre, 1; Order of Crown of Italy, 1; Order of St. Anne (3rd Class, with Swords), 2; St. George's Medal, 1; Order of St. Vladimir, 1; Chev. de l'Ordre de Léopold et Croix de Guerre, 1, and L'Ordre de la Couronne, 2 (both conferred by King of Belgians); Order of the White Eagle, 1; Order of St. Sava, 5th Class (conferred by King of Serbia), 1; Jutland Bank Battle Despatch: Commended, 1; recommended, 3; Mentioned in Despatches, 45.

London (Royal Free Hospital) School of Medicine for Women.—Honours have been conferred on former students during the past year as follow: C.B.E., 5; O.B.E., 1; M.B.E., 3; Cross of the Legion of Honour, 1.

St. Mary's.—The completed figures are: Joined, 600; died, 38; wounded, 37; prisoners or missing, 16 (of whom 5 have been repatriated). Honours: C.B., 6; C.M.G., 7; M.C., 26; D.S.O., 19; C.V.O., 2; O.B.E., 2; Order of the White Eagle, 4th Class (with Swords), Serbian, 2; Ordre de la Couronne (conferred by the King of the Belgians), 1; Légion d'Honneur (Croix de Guerre) (conferred by the President of the French Republic), 1; Order of St. Sava, 5th Class (Serbian), 1; Order of the Nile (conferred by the Sultan of Egypt), 1; Silver Medal for Valour (Italian), 1; Mentioned in Despatches, 128.

Middlesex.—The completed figures are: Joined, upwards of 500; died, 30. Honours (known): 46.

St. Thomas's.—The completed list up to Sept. 28th is as follows: Joined, 1115; died, 57. Honours: V.C., 1; G.C.M.G., 1; K.C.B., 1; K.C.M.G., 3; C.B., 5; C.M.G., 15; D.S.O., 25; D.S.C., 1; M.C., 49 and 4 Bars to M.C.; C.I.E., 3. Mentioned in Despatches and for valuable service: 158 men, 224 times. The Foreign Honours include: French, 12; Serbian, 7; Belgian, 3; Egyptian, 6; the Order of the Hospital of St. John of Jerusalem, 5. And 12 have been among the promotions in, and appointments to, the Order of the British Empire for services rendered in connexion with the war.

University College Hospital.—Since the commencement of the war the number of past and present students who have joined the Navy and Army is 702, and the number of deaths have been 29. The following distinctions have been gained: K.C.M.G., 1; C.M.G., 16; C.B., 4; D.S.O. (Bar 1), 17; V.C. (Clasp), 1; Legion of Honour (Croix de Commandeur), 1; Croix de Guerre, 3; Military Cross (Bar 3, Second Bar 1), 31; Mentioned in Despatches (20 twice, 5 three times), 129; Order of the White Eagle, 4th Class, with Swords (Russian), 1; Order of St. Stanislas, 2nd Class, with Swords (Russian), 1; Order of St. Stanislas, 3rd Class, with Swords (Russian), 1; Order of St. Sava, 3rd Class (Serbian), 1.

NEW HOSPITAL FOR SHELL SHOCK CASES.—A new hospital for discharged neurasthenic sailors and soldiers has been opened at Bray Court, Maidenhead. The management of the institution has been placed by the Ministry of Pensions in the hands of the National Hospital for the Paralysed and Epileptic, Queen-square, London, W.C., which is the largest and oldest hospital for the treatment of the many diseases of the nervous system. At present accommodation for the treatment of 50 patients has been provided. Within the large building, outbuildings, and extensive grounds there is ample room for arrangements for re-education and teaching of suitable trades.

SCOTTISH WOMEN'S HOSPITALS FOR HOME AND FOREIGN SERVICE.—The London units, under the London Society of the National Union of Women's Suffrage Societies, are appealing for funds to meet the increased drain on the resources in Macedonia, which continues, although the fighting is now happily at an end. Medical and surgical stores need constant renewal. Contributions should be sent to Lady Cowdray or Miss T. Gosse at 66, Victoria-street, S.W. 1.—Dr. Elinor Rendel has gone out to Macedonia as junior surgeon to the Elsie Inglis unit of the Scottish Women's Hospitals. This unit was the only field hospital attached to the Jugo-Slav Division during the Franco-Serbian offensive. The hospital camp was, when the last news came through, at Dragomantsi, north of Vodena, and a month ago a new station, served by motor ambulances, was established still nearer to the front. Miss Rendel has already seen active service. She was still a student at the London School of Medicine when she went out to Russia in August, 1916, with Dr. Elsie Inglis. As dresser and X ray assistant she worked on the Russo-Roumanian front, and gained a great deal of campaigning experience before she returned to complete her studies.

THE LATE DR. JAMES HAMILTON.—James Hamilton died on Sept. 24th at his residence, Chapel Hill House, Huddersfield. He was the youngest son of the late Rev. William Hamilton, of Omagh, co. Tyrone, and a brother-in-law of Mr. James Ross, Senior Inspector of National Schools, Shantallow, Londonderry. He studied at Queen's College, Galway, the Carmichael Medical School, Dublin, and Glasgow, graduating M.D., B.Ch., B.A.O. of the Royal University in 1889. For some time he practised in Leeds, where his professional skill and kindly qualities gained him the respect of patients and colleagues.

SIMPLE FIRE PRECAUTIONS FOR THE COMING WINTER.—The British Fire Prevention Committee issues its timely reminder of the principal safeguards against fire in the form of a small poster (No. 32), which will be sent gratuitously to anyone who applies to the committee in writing, enclosing an addressed and stamped envelope. In many households the head of the family is now serving with the colours or away on war work, and the matter of fire precautions in the household is therefore left in less experienced hands. Heating and lighting arrangements are now being overhauled in many establishments with the view of economy for the coming winter, and the safeguards on which the committee lays stress can be attended to at the same time. The address of the British Fire Prevention Committee is 8, Waterloo-place, London, S.W. 1.

"Audi alteram partem."

HYPNOSIS IN HYSTERIA.

To the Editor of THE LANCET.

SIR,—Both Major W. Brown and Captain J. R. O'Brien raise an interesting point in discussing the rôle of hypnosis in hysterical people, the former when he states that "only hysterical patients can be hypnotised," and the latter when he takes exception to this on the ground that "80 per cent. of all mankind can be hypnotised." The essential point to be realised is, that the factor in hysteria that lends itself to hypnotism is suggestibility, and this factor is present in all mankind, though in varying degrees. Given a defective environment during upbringing—defective as far as the environment in which the child when grown up will have to live and work—then there is liable to be a lack of emotional control and an associated high degree of suggestibility which in the course of time is likely to give rise to obtrusive hysterical symptoms. In the educated adult who has been correctly orientated there is a considerable degree of emotional control, and suggestibility, though present, is of low intensity. But it is present, and in that such a man is emotional and is suggestible at all he has the factors of hysteria present. In other words, all human beings are hysterical to a certain extent, in that they are human. But in only a few people, comparatively speaking, do the emotions through lack of control, and suggestibility through its intensity, manifest symptoms in a manner necessitating medical treatment, and in such people no new factors are being encountered, but factors which, present in all, are intense in some only. So that it is not that only hysterical patients can be hypnotised so much as that hysterical patients are *easily* hypnotised; people who have not manifested hysterical symptoms, being less suggestible, are less easily hypnotised. But, as Captain O'Brien's statistics go to show, the great majority of men can be hypnotised in some way or another.

If Major Brown had said "only hysterical *people* can be hypnotised" there would have been no incompatibility between his statement and Captain O'Brien's; the majority of mankind, though having all the factors of hysteria, go through their lives without showing obtrusive symptoms, and so without their coming under medical treatment.

The value of hypnotism in hysterical patients is, in my opinion, open to doubt, for in such cases there is a degree of suggestibility that has proved itself to be morbid, and in playing on this suggestibility there is a possible risk of increasing its intensity; by so doing the patient, though relieved of his symptoms, may be left more hysterical at the end of treatment than at its inception. The rational method is surely not the empirical method of suggestion from without, which in addition to the above objection has the further drawback of the liability to relapse, but the resolution of the symptoms through the patient's own consciousness, a very much harder method but one which is more liable to be permanent as far as those particular symptoms are concerned.

In his letter in THE LANCET of Sept. 28th Major Brown admits the risk of making a hysterical patient more hysterical as a result of hypnosis, and the methods of hypnotism that he himself employs are undoubtedly directed towards a lessening of this risk. But still the essential fact is unaltered; in any case that has been hypnotised the suggestibility previously possessed by the patient, and active in the genesis of his hysterical symptoms, has been picked out and utilised by this method, and however carefully the operator may have brought the patient out of the hypnotic state the very fact that the morbid dissociation has been resynthesised at all indicates a reactivation of this already morbid degree of suggestibility, and is therefore to be deprecated. It is noticeable that the modifications used by Major Brown in the process of hypnosis are directed to the end of an appeal to the patient's own consciousness and a lessening of the purely hypnotic suggestion. The more successfully this is carried out the more satisfactory will be the result, until the ideal will be attained and the hypnotic element completely eliminated.—I am, Sir, yours faithfully,

DONALD E. CORE,
Captain, R.A.M.C. (T.F.).

Manchester, Oct. 1st, 1918.

THE PROPHYLAXIS OF VENEREAL DISEASE.

To the Editor of THE LANCET.

SIR,—Long discussion following Sir Bryan Donkin's letters early last year showed that there are now a number of medical men who have the courage to advocate the abandonment of the neglect of this the most potent weapon against the spread of venereal diseases; but it is not clear that any very active steps have yet been taken by the medical profession in this direction. Unless the present golden opportunity is utilised of making these simple antiseptic methods generally known, the end of the war is certain to cause venereal diseases to be more widespread than ever, as after many previous wars. On the other hand, if all the Army could be instructed regarding the prophylaxis against venereal diseases this life- and health-saving knowledge will become widely diffused among the general population on demobilisation, and a great reduction, instead of an increase, of the scourge will be effected.

Really the case for adopting these prophylactic measures may be briefly summarised in the following propositions: 1. Venereal diseases are causing a most serious loss of manpower at a crisis in our national history, as shown by the statement of the Under Secretary for War that no less than 54,884 soldiers were admitted to hospital for these diseases in 1917 alone, while many innocent women and children will certainly be infected after the war. 2. The use of Metchnikoff's 30 per cent. calomel ointment before and after exposure to infection and of a 1 in 2000 solution of permanganate of potash for washing after exposure have been proved to greatly reduce venereal infection by the experience of the United States Navy and that recorded by Dr. G. Archdall Reid in THE LANCET of Nov. 3rd, 1917. The recent figures of Rigg relating to several thousand exposures showed that only 0·08 per cent. of infections occurred after disinfection within one hour, 0·65 per cent. after from two to four hours, but 7·80 per cent. after over ten hours, or a reduction of nearly 99 per cent. by very early disinfection. 3. The question is essentially a medical one, and the fact that a single innocent child can be saved from suffering from the most serious and deadly of these diseases to my mind far outweighs any moral arguments against placing prophylaxis against these affections on the same footing as those against all other infectious diseases, while the following plain statement regarding syphilis of Professor Sir William Osler, "Get people to realise that it is a great communicable disease, two-thirds of the victims of which are innocent, and much will be done to break down the present barrier of ignorance and false sentiment," is, I think, unanswerable.

I therefore strongly urge that the greatest national service the medical profession can render at the present time is to form an active society (unless such already exists) to adopt the plan of the committee of medical men in Victoria[1] when the Victorian Government hesitated in the matter—namely, to publish and distribute widely a pamphlet, in which it is first clearly set forth that sexual incontinence is totally unnecessary and best avoided altogether; but that in the case of everyone who fails to be continent it is their duty to the nation, to themselves, and to possible future innocent victims of their errors immediately to use the simple means of disinfection set forth in the pamphlet to diminish the chances of their becoming infected, although they must remember that it is not an absolute preventive and will not make them completely safe against the penalties of their offences against morality. If every soldier returning to Great Britain, either on leave or eventually on demobilisation, is given such a pamphlet an immense amount of disease, and subsequent infection of innocent women and children, will be avoided, and the reproach recently levelled by certain colonial troops against London as "the plague spot of the world" may be partially removed.

As action rather than discussion is now urgently needed, and the writer is not in a position to take an active part in such a crusade, I shall be glad to contribute through you, Sir, to any society or body of medical men who will undertake early action, beginning in London, on some such lines as the above, the sum of £100 towards the expenses of the propaganda. To show that I have some qualifications for expressing an opinion on the matter, I subscribe myself

M.D., F.R.C.P., F.R.S.

Sept. 28th, 1918.

MEDICAL CERTIFICATES PRIOR TO MARRIAGE AND VENEREAL DISEASES.

To the Editor of THE LANCET.

SIR,—Recently I attended a conference of the Yorks County Branch of the National Council for Combating Venereal Diseases. At this meeting, which was addressed, amongst others, by a Mrs. Pendlebury, who is, I understand, an organiser of the National Council, one statement was made which is of such importance that I now bring it before your readers' notice—namely, that it was part and parcel of the National Council's campaign against venereal diseases to urge the policy of compulsory medical examination of both parties prior to their entering into a marriage contract, for this is what medical certification means when stripped of all verbiage.

I think, Sir, the public are entitled to an authoritative statement from the National Council on this part of their programme.—I am, Sir, yours faithfully,

A. B. DUNNE, M.B., B.C. Cantab., &c.

Doncaster, Sept. 25th, 1918.

*** We are informed by the General Secretary of the National Council for Combating Venereal Diseases that though the Council has, up to the present, passed no resolution advocating legislation on the subject of health certificates before marriage, it recommends its speakers, in general terms, to set forth the advisability of parents making inquiries as to the health of the intended partner in marriage.—ED. L.

CHRONIC INTESTINAL STASIS.

To the Editor of THE LANCET.

SIR,—In his instructive and suggestive paper on this subject which appeared in your issue of Sept. 28th, Sir W. Arbuthnot Lane carries his teaching a step further. We are now able to appreciate the effects of chronic intestinal stasis not only clinically, but even microscopically. The clinical manifestations which he originally described are now generally recognised, and for the most part are attributed to their undoubted cause. The present paper is the logical outcome of what he has already taught, and he will not be surprised if, in common with its predecessors, portions of it are "received with ridicule": for logic thrives badly in an atmosphere of jealousy. We are now in a position to estimate all or nearly all the pathological miseries which follow in the train of chronic intestinal stasis, but we are not, it seems, very much nearer the goal of all this excellent work of Sir W. Arbuthnot Lane—namely, the prevention of the condition the causes and consequences of which he describes so graphically. The *causa causans* is the upright posture, leading to the development of supporting bands which produce festooning of the transverse colon and other forms of obstruction. An obvious remedy, therefore, would be for man to revert to the posture and gait of his quadruped ancestors, a reversion which in many cases—those, for example, of Sir W. Arbuthnot Lane's detractors—would be eminently suited to their intellectual capacities.

Another lesson which we might profitably learn from a consideration of the said quadrupeds is that the damnable heritage of the colon would be infinitely less damnable if we treated ours as they treated theirs. They treated theirs to long periods of complete rest; not from religiosity, nor from diabetes, but from necessity. They went for several days without food. We never do. In us, the jejunum is said to be always empty; the ileum never. And the ileum is never empty because its contents are ponded back by the accumulation at the cæcum and onwards. If, therefore, man will not return to four-footedness and would avoid intestinal stasis he must fast. But he won't; nothing will induce him to. When his whole intestinal canal is screaming for repose he responds by giving it, in accordance with the highest medical advice, beef-tea at 11 and Benger at bedtime. Moses was a great sanitarian; but he appointed only one day of atonement by fasting in the year. If the new Ministry of Health would appoint at least 52, and enforce them, it would bring Sir W. Arbuthnot Lane's teaching to brilliant fruition.

I am, Sir, yours faithfully,

Harley-street, W., Sept. 30th, 1918. LEONARD WILLIAMS.

To the Editor of THE LANCET.

SIR,—If comment be permitted upon Sir W. Arbuthnot Lane's remarks on the above subject, I should like to point out that, whatever other factors contribute to the induction of intestinal stasis, the most important one has been omitted from his paper. It may be that he does not consider it of primary importance but only a minor concomitant. Subacute chronic inflammation of some portion of the alimentary tract, set up by some infection, precedes the stasis. The provocative bacteria, varying in different cases, are generally those against which the patient has inherited a poor resistance, or his blood may have lost some of its normal bactericidal power through depressing agents—e.g., sedentary habits, bad air, worry, improper feeding, &c. The muscular coat of the intestine grows torpid, œdematous through infiltration from the adjacent sodden mucous membrane, or in obedience to inhibiting stimuli from the nerve-centres—Nature's effort to avoid the pain of irregular peristalsis in the inflamed areas.

I have examined many specimens of intestinal mucus obtained by colon-irrigation from cases of stasis to ascertain their bacterial flora, generally for the purpose of getting a clue to some arthritic trouble. The commoner catarrhal bacteria (capsulated streptococci, staphylococci, *B. mucosus capsulatus*, influenza-like bacilli, pneumococci, enterococci, &c.) have been most frequent and numerous, often equalling the coli group in numbers. Where inoculation treatment has been successfully applied one interesting incident has often been reported to me. Some cases of most inveterate constipation, of almost lifelong duration, have been replaced by normal action of the bowels. Apart, then, from congenital defects, I honestly believe that stasis arises from causes outside the province of the surgeon, and should not be submitted to his anatomical readjustments until milder measures have been well and thoroughly tried.

I am, Sir, yours faithfully,

Bentinck-street, W., Sept. 28th, 1918. H. LYON-SMITH.

DRUG IDIOSYNCRASY.

To the Editor of THE LANCET.

SIR,—The following case of drug idiosyncrasy is perhaps worth recording:—

The patient, a baker's assistant, female, about 23, strong and well nourished, came into an institution last October in a "stuporous" condition. In 48 hours she showed intelligence and reported like attacks at intervals for the past six months, dating apparently from an air raid. There was marked constipation. Among other things she was put on a potassium bromide mixture, 10 grains to the ounce, t.d.s. On the second morning she had developed a profuse roseolar rash. The bromide was discontinued, with disappearance of the rash the following morning. She was tried with strychnine and belladonna, but responded satisfactorily only to enemas. The morning following the administration of belladonna another rash, mainly on the chest and extensor aspects, was observed, differing, however, from the first rash. On this drug being dropped, the second rash disappeared within 24 hours. I was then away for a day or two when by some inadvertence the patient, who had relapsed into her stuporous condition, was again put on bromides, with the rapid supervention in a few hours of a third skin manifestation. I stopped the bromides and the rash went away within 24 hours.

As this patient had been treated with soap enemas with some success, I incline to the view that the rashes were drug rashes, for when she was given a simple tonic and rest in bed no further skin manifestations occurred, and she was discharged in about ten days after the last one had been observed. The seizures were not definitely epileptiform.

I am, Sir, yours faithfully,

T. S. GREENAWAY, M.R.C.S., L.R.C.P.

London, W., Sept. 26th, 1918.

THE FUTURE OF THE MEDICAL PROFESSION.

To the Editor of THE LANCET.

SIR,—No one who knows Professor Benjamin Moore and Mr. Charles Parker can doubt their high aim in endeavouring to eliminate undesirable competition amongst professional men by the introduction of a whole-time salaried service. Those of us who are in daily touch with general practitioners fail, however, to recognise as true to life the picture these idealists have drawn for themselves of our profession as a jostling crowd of men with strong muscles and plausible tongues struggling for patients and fees. If there is a small minority of evil-doers who take advantage of existing opportunities for greedy advancement our con-

tention is that these evil instincts will not be abolished or their owners be deprived of opportunities of using them by the revolution of our system of remuneration which is proposed by the State Medical Service Association. Robust health and plausible tongues would still enable the unscrupulous amongst the salaried officials set up under the proposed scheme to gain promotion at the expense of men with better brains and more delicate consciences. Is not a higher salary a "direct personal pecuniary gain"? Do all the better-paid posts in the Army and the Church fall to the men of brain and conscience? Have plausible tongues no influence on promotion in the Civil Service or in the world of politics?

If the State Medical Service Association wishes to convert the public and the profession to the idea of a whole-time salaried service of medical practitioners it must find a more convincing argument than that thereby undesirable competition will be eliminated. The public must be convinced that it will be better served by salaried medical officers; the profession must be shown that it will have greater opportunities of freely exercising its beneficent functions. Neither the public nor the profession is, I believe, satisfied on these points by any arguments at present put forward.

I am, Sir, yours faithfully,

Sept. 20th, 1918. LAURISTON E. SHAW.

THE MANAGEMENT OF LUNACY PATIENTS.

To the Editor of THE LANCET.

SIR,—In criticism of Dr. Lionel Weatherly's statements concerning medicinal treatment in rate-supported mental hospitals, may I point out that, first, it is not an acknowledged fact, nor is it a fact at all, that illness is more rife amongst the insane than among the general population. There is, indeed, a large group of diseases which is responsible for most of the illness in the general population, from which mental patients are practically immune, which easily more than outweighs that group to which they are specially prone. Secondly, assuming that 4*s.* 4*d.* is the average amount per patient per annum spent on the item "surgery" in the maintenance account (and in many cases it is much more), this is a very much larger sum than is spent on the corresponding item under the Insurance Act, which shows how generously and well these patients are treated in comparison with the general public of the same class; and on a comparison of the average number on the sick list in a public mental hospital with the average number on the sick list of the panel doctor it would appear that the mental hospital still holds its own. I think it is quite clear from statements in Dr. Weatherly's letter and brochure that he is not familiar with the amount of honest and earnest work being done in these institutions (which he is so desirous of abusing), without display, publicity, or the stimulus of popular favour.

There are many points in Dr. Weatherly's book with which all of us must agree, but on this point we can only regret that he has gone out of his way to present to the public a picture which can do nothing but harm, and is contrary to the true condition. Unfortunately, that which is contrary to the truth has got the start.

I am, Sir, yours faithfully,

JAMES R. WHITWELL.

St. Audry's Hospital, Melton, Suffolk, Sept. 25th, 1918.

To the Editor of THE LANCET.

SIR,—I have just read with much interest Dr. Lionel Weatherly's book, "A Plea for the Insane." In vigorous and uncompromising style he trounces laws, public authorities, and individuals in a way that is quite agreeable to read—to those, at any rate, who agree with him. But better than this, he makes many valuable suggestions for the reform of the law and procedure involved in the care of the insane, and he also criticises the present-day treatment. Coming from a man of his experience and astuteness, these suggestions must carry weight; and as one who, like most practitioners, has practical interest in these matters, I should like to bring forward at the present time some points which appear to me to be of particularly practical importance, especially now that the reform of the education and practice of our profession is in the front of the background.

First of all, as to the early diagnosis of cases. I am, of course, only speaking for myself as a general practitioner, but I think from what I know of the views of others that I am not alone in my opinion. Our great difficulty is the recognition of the very earliest stages of mental disease. In any disease this is often a difficult matter and one which faces the general practitioner more than any other member of the profession. In mental disease early recognition is of vast importance, and failure to recognise in due time may easily have disastrous effects. We, with our opportunities as family practitioners, ought to be able to recognise mental disease early, but our difficulty, I am afraid, arises from want of sufficient training. I feel quite sure that we do not, in the early days of our medical life, give nearly sufficient attention to this branch of our work, and I hope that when the medical service of the country is reorganised opportunities will be provided for post-graduate study at special mental hospitals or clinics. But we have still another difficulty in diagnosis, and that is the finding of a suitable consultant. This arises partly because the public have an idea that when an alienist is called into consultation he is almost sure to recommend the patient to be removed to an asylum, just in the same way as they are afraid to have a surgeon called in for fear that he may recommend an operation; and partly also our difficulty is that consultants who are at the same time mental specialists and general physicians are few and far between. I have the very highest regard for many of the specialists in this department, whom it is my privilege to know, but I cannot get away from the feeling that there is a tendency amongst them to specialise too much; and this partly, I think, because they specialise too soon. A not long qualified man takes a post as assistant at an asylum. In time to come he is senior assistant, superintendent, and then consultant. I always have contended that a specialist ought to be evolved, not created, and the first stage in his process of evolution should be five or six years of general practice. It may seem a long time, but I do not think too long. There is no doubt that not only is the general practitioner too ignorant of the symptoms and treatment of mental diseases, but the asylum medical officer is apt, at any rate, to be equally ignorant of the treatment of many of the diseases from which his patients suffer. This has, on various occasions, been painfully brought to my notice. I think it arises, not only from want of sufficient experience in general practice, but from a system of routine and organisation fatal to individualism, originality, and enthusiasm.

Having made our diagnosis, our next difficulty is the finding of a suitable place for treatment. The ordinary nursing home, which has unfortunately come to be much abused, not only by neurologists but by all sorts of medical men, is, as Dr. Weatherly so plainly points out, quite unsuitable—not only unsuitable but positively injurious. I have known cases put into nursing homes, and there become certifiable, which had they only been in proper surroundings would in all probability never have arrived at such a deplorable state. The recognised institutions provided for this purpose are too few to be generally available, and personally I have experienced great difficulty in finding a suitable private house to which to send early cases with advantage to the patient. Too many of them are run purely as financial undertakings; and again, for the majority of one's patients—the great majority—the cost of these single houses is much too heavy. The result only too often is that the case drifts on until it becomes certifiable. Would it not be possible to have an official list of suitable houses to which medical men could refer? Nothing can be more distressing to a medical man than to watch a case that he feels sure with proper treatment would probably get well, being allowed, for want of suitable means of treatment, to drift on until it gets into the land of the certified, from which few return without some trace of their sojourn.

How long are patients and their friends and relations, not to mention their medical attendants, to be tortured and worried for want of a simple alteration in the law which would allow of notification as well as certification? The remedy is so simple, and the difficulty so negligible, that it seems to me extraordinary that the public and the profession should so long have put up with the want of it. I hope that Dr. Weatherly's powerful plea for this reform will not be long in having effect.

I am, Sir, yours faithfully,

Bradford-on-Avon, Sept. 18th, 1918. CHAS. E. S. FLEMMING.

MANGANESE POISONING.

To the Editor of THE LANCET.

SIR,—With reference to the letter of Dr. James Gairdner in your issue of Sept. 28th with the above title, and in view of the extensive use of colloidal manganese at the present time by intramuscular injection in furunculosis, acne, eczema, gonorrhœa, and generalised systemic infections, we should like to point out that in the colloid state manganese is for all practical purposes non-toxic.

Before submitting samples to the medical profession for clinical use physiological experiments were undertaken by Professor R. Tanner Hewlett, of King's College, who in July, 1918, found that 11 c.cm. of collosol manganese injected intravenously into a rabbit weighing 2 kg. produced no ill-effect. The dose found by clinical experience to produce best results is 0·5 c.cm. to 1·5 c.cm., and reports (as already mentioned by Sir Malcolm Morris and other practitioners in the medical journals) almost invariably show marked constitutional improvement after the injections.

The work of many investigators (Bertrand, Perrin, and others) seems to show that colloidal manganese acts as a peroxidase. Over-stimulation of the oxidase system is, of course, to be avoided and, if we might venture to offer a suggestion, the dosage ascertained by practical experience should be adhered to, though in the symptoms of mustard gas poisoning as much as 3 c.cm. is clinically advised.

I am, Sir, yours faithfully,

J. F. WARD,
Manager, The Crookes Laboratories.

50, Elgin-crescent, W., Sept. 30th, 1918.

METHODS OF CONTROL OF FRAGMENTS IN GUNSHOT WOUNDS OF THE JAW.

To the Editor of THE LANCET.

SIR,—I am gratified to know that Mr. C. H. Bubb, in his letter in your issue of Sept. 28th, agrees in the main with the methods I described in my communication to THE LANCET of Sept. 7th. With regard to the points on which Mr. Bubb disagrees with me, I would say: (*a*) The four-tail bandage, correctly applied, I only advocate as a "*first aid*" method. This, I think, I made clear. (*b*) To suggest that any bandage, webbing, elastic or otherwise, could possibly do what a screw lever splint does, only shows that your correspondent is not familiar with the splint. The screw lever splint exerts a *forward* pressure, opposes the action of the depressor muscles, and yet permits of free function of the jaw—things which no kind of bandage could possibly do. (*c*) The "perforating bolt and nuts" for symphysis fractures is introduced posterior to the infected area, and was designed with the precise object of leaving the latter area entirely free from any apparatus whatever. The bolt does not perforate the buccal cavity, as his circumferential wires do, and the operation is done entirely aseptically—points which Mr. Bubb evidently failed to grasp. (*d*) Mr. Bubb is surprised that I made no reference to the "open-bite" method of splinting; but I regard it as unsound and never use it, and the communication only dealt with my own methods—methods which I believe to be original.

I am, Sir, yours faithfully,

Frognal, Sidcup, Oct. 1st, 1918. H. P. PICKERILL.

THE death occurred of Clara Hind, L.R.C.S., L.R.C.P.E., of Ockley Sanatorium, on Sept. 15th. She commenced her career as a nurse and was some years at Nottingham, when she obtained her full training in medical and surgical nursing. She then trained in midwifery, getting the L.O.S. certificate. Later she was appointed matron of the Clapham Maternity Hospital, which post she held for five years, when she entered as a medical student at the London School of Medicine for Women and the Royal Free Hospital. She qualified in 1901, and then devoted herself especially to the open-air treatment of phthisis. She was appointed resident physician to Rudgwick Sanatorium, and later founded the sanatorium at Ockley, which she managed for 15 years. Her twofold training as doctor and nurse made her most fitted for such work, and her sudden death is a loss to preventive medicine in her specialty. Her help in the training of women medical students, midwives, and nurses in midwifery was invaluable. She never lost touch with the Clapham Maternity Hospital, and later became a physician to out-patients, and also a trusted and valued member of the committee, by whom her loss will be deeply felt.

THE SERVICES.

INDIAN MEDICAL SERVICE.

Temporary I.M.S. Officers.—It has recently been decided that certain classes of temporary officers of the Indian Medical Service may re-engage under the terms of the Army Department letter of Feb. 9th, 1915, provided they have been continuously employed since their first appointment. These classes are: (*a*) Those who were engaged by the Director-General, Indian Medical Service, for service overseas prior to the issue of the letter quoted above, as well as those engaged under the terms of that letter; (*b*) those who were engaged by the Bombay Relief Fund for service in Egypt, and subsequently re-engaged by the Government of India. The officers referred to above should accordingly be paid at the rate of 24*s.* per diem, whether serving in India or overseas.

Indian Defence Force Medical Corps.—The Indian Defence Force Medical Corps has just been created. Persons holding the following medical and surgical qualifications may be granted commissions: (*a*) Registrable in the United Kingdom; (*b*) L.M.S. Madras; (*c*) Membership of State Medical Faculty, Bengal; (*d*) Memberships of College of Physicians and Surgeons of Bombay; (*e*) American diplomas, the courses of study for which are recognised by the General Medical Council. Commissions in the I.D.F.M.C. will be governed by the regulations applying to commissions in the I.D.F. generally so far as they are applicable. Commissions in the I.D.F. may be on the General Service or Local Service List. Officers on the General Service List will be required to serve in any part of India. Officers on the Local Service List will be required to serve in one locality only. Officers of the I.D.F.M.C. will be granted the following substantive ranks: Lieutenant on first appointment, Captain after three years' service, Major after 12 years' service, and Lieutenant-Colonel after 20 years' service. Each step in promotion will only be granted if recommended by the officer commanding. Service as medical officer of Volunteer units will count for the purpose of this Regulation as service in the I.D.F.M.C. Officers of the I.D.F.M.C. will be placed under the orders of officers commanding station hospitals where such hospitals exist. At stations where there are no station hospitals they will be attached to units of the I.D.F. If not attached to a unit of the I.D.F. officers of the I.D.F.M.C. will be on the Supernumerary List.

ROYAL NAVAL MEDICAL SERVICE.

Temp. Surg. R. E. R. Burn, who has been invalided on account of ill-health contracted in the Service, retains his rank.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. G. J. A. Ormsby relinquishes the temporary rank of Colonel on re-posting.

The undermentioned relinquish the acting rank of Lieutenant-Colonel on re-posting: Major E. B. Booth, Temp. Capt. H. Faulkner.

To be acting Lieutenant-Colonels whilst in command of a Medical Unit: Major M. F. Grant, Capt. (acting Major) E. Phillips.

Temp. Capt. A. N. Bruce to be acting Lieutenant-Colonel whilst specially employed.

Temp. Capt. L. Leslie relinquishes the acting rank of Major on re-posting.

To be acting Majors: Capt. D. Bell; Temp. Capts. O. J. Day, W. L. Lyall, J. D. Cooke, M. Fitzmaurice-Kelly, G. G. Anderson, J. R. Davies.

Temp. Capt. E. L. Warner, Canadian A.M.C., to be temporary Major.

Temporary Lieutenants to be temporary Captains: J. Martin, J. B. Wilkie, D. Young, M. B. Reichwald, H. L. Pearson, C. F. Curtis, T. Craig, D. M. Cox, J. S. Crichton, D. T. Evans, H. Graham, S. A. Furlong, M. Dockrell, S. M. Vassallo, G. W. B. Shaw, H. H. Molloy, G. M. Grundy, R. G. Meyer, F. W. Emery, F. M. H. Sanderson, L. E. C. Handson, E. G. Hodgson, H. Farncombe, A. E. Clark, C. W. Coghlan, H. D. Pollard.

To be temporary Captains: G. B. Wilkinson, H. McKinnon (Canadian A.M.C.), E. A. Aylward, W. J. Woodman (late Captain, R.A.M.C., T.F.), W. G. Lidderdale, E. S. Holloway, B. Beamish, S. L. Haslett, F. M. Harvey, J. F. Bullar, A. S. Allan, W. Hughes, P. Daly, L. J. Hood.

To be temporary Honorary Captains: S. J. Cattley and J. R. Taylor.

To be temp. Hon. Lieutenants: F. A. Georger and B. D. Brooker.

Late temporary Captains granted the honorary rank of Captain: E. A. Pearson, E. G. H. Weir, and A. M. J. Halligan.

To be temporary Lieutenants: D. H. Vickery, T. M. Richardson, L. Milburn, W. Bligh, S. F. Breakly, H. T. O'Neill, C. H. Lee, R. Lawrence, W. A. Mein, J. Black, A. D. Pringle, H. R. F. Towne, A. I. Girdwood, F. Aitken, R. M. Moore, L. N. H. Biggs, H. C. Sutton, H. Abernethy, W. K. Anderson, C. Blake, E. S. Verdon, S. Wilton, C. R. Kidd, A. I. Aylmer, E. W. Sharp, J. G. Louden, A. Macintyre.

Officers relinquishing their commissions:—Temporary Captains granted the honorary rank of Captain: T. C. Pocock (on account of ill-health contracted on active service), S. C. Westwood, T. W. Bailey (on account of ill-health), C. A. Wickham, J. W. Wayte (on account of ill-health caused by wounds); Temp. Capts. F. H. Cooke, W. H. Parsons, A. G. Graham, S. C. Shanks, P. Daly, F. J. McCarthy, A. D. Howard, W. E. Peck, B. H. Swift, J. F. Allen, C. Wace, T. S. S. Holmes, T. E. Parker, F. S. Noble, H. O'Neill, R. McCaffrey, A. P. Woollright, F. L. McKinnon, J. H. Mayston; Temp. Lieuts. T. E. Lister, F. W. Chesnaye, H. Leach, W. H. Woodyer, P. T. J. O'Farrell, A. Rogers, G. Burnet, K. D. Marriner, C. L. Birmingham, T. C. D. Cathcart; Temp. Hon. Lieut. C. E. Fearn (on account of ill-health, and is granted the honorary rank of Lieutenant).

SPECIAL RESERVE OF OFFICERS.

Lieut. D. J. Valentine to be acting Major.

Capt. N. M. Lewis relinquishes his commission on account of ill-health, and is granted the honorary rank of Lieutenant.

Capt. E. J. Bradley relinquishes the acting rank of Major on re-posting.

To be Lieutenants: R. B. MacGregor (from Edinburgh University Contingent, O.T.C.); J. F. Cunningham, W. H. Duff, A. K. I. Jones (from University of London Contingent, O.T.C.); A. M. Dugan (from Aberdeen University Contingent, O.T.C.); W. A. Hewitson (from Durham University Contingent, O.T.C.); G. R. Baxter (from Leeds University Contingent, O.T.C.); J. M. Macpherson, A. M. Davidson; and N. B. Peacock, W. Napier, A. S. Goudie, J. W. Mackay, J. B. Potter, W. Scotland, D. Finlayson, F. K. MacMillan (from Glasgow University Contingent, O.T.C.).

TERRITORIAL FORCE.

Major T. Duncan relinquishes his commission on account of ill-health, and is granted the honorary rank of Major.

Captains to be acting Majors whilst specially employed: A. L. Sharpin, G. B. Pritchard, G. H. Dominy, H. Connop, J. Walker, W. A. Campbell.

Capts. (acting Majors) C. S. P. Black and P. S. Martin relinquish their acting rank on ceasing to be specially employed.

Capt. W. Duncan to be acting Lieutenant-Colonel whilst specially employed.

Major F. G. Bushnell and Capt. C. N. Chadborn are seconded for duty overseas.

Capt. R. Richards is restored to the establishment.

Capt. (Brevet Major, temporary Lieut.-Col.) C. H. S. Frankau relinquishes the temporary rank of Lieutenant-Colonel on ceasing to command a Casualty Clearing Station.

Capt. N. C. Rutherford to be acting Lieutenant-Colonel whilst commanding a Field Ambulance.

Capt. E. D Gairdner, D.S.O., to be Major.

Lieut. W. E. Evans to be Captain.

ROYAL AIR FORCE.

Medical Branch.—Granted temporary commissions as Captains: E. G. Fearnsides (to be hon. Major), R. B. Lilly, H. P. Helsham (Capt., R.A.M.C.), B. H. Swift, M. E. H. Wale. Granted temporary commissions as Lieutenants: E. E. Rollins, A. E. Collie, E. F. Wilson, S. A. Clark.

Dental Branch.—Granted temporary commissions as Lieutenants: H. O. Salt, H. H. Chapman, G. H. W. Randell.

Medical News.

UNIVERSITY OF DURHAM: FACULTY OF MEDICINE.—At a special Second Examination for the degree of Bachelor of Medicine the following candidates were successful:—

Anatomy and Physiology.—John Neville Alexander, Francis Joseph Benjamin, Oliver Colville (second-class honours), Edward Thomas Colville (second-class honours), Thomas William King Dunscombe, Donald Falconer Hocken, James Joseph Laydon, Morris Mickler, Kenneth Moncrieff, Robert John Perring, and Sydney Terry Pybus.

UNIVERSITY OF BRISTOL.—At a supplementary First Examination for the degrees of M.B., Ch.B., recently held, Eric Cecil Keevil Kenderdine and Carrie Hooper Osmond were successful.

THE BELL FUND.—Dr. S. A. Kinnier Wilson asks us to acknowledge a donation to the Dr. J. H. Bell Fund of £1 1s. from Dr. S. H. Belfrage. Subscriptions should be sent to Dr. Wilson, at 14, Harley-street, London, W. 1.

GUY'S HOSPITAL MEDICAL SCHOOL.—The following scholarships have been awarded:—Senior Science Scholarships for University students: £75, Joshua Harold Burn, Emmanuel College, Cambridge; £35, Malcolm Henry MacKeith, Queen's College, Oxford. Junior Science Scholarships: £120, Edwin Charles Warner, Guy's Hospital; £50, Maurice Burkett Goolding. Guy's Hospital Scholarship in Arts: £100, Charles Skinner Hallpike, St. Paul's School.

ST. BARTHOLOMEW'S HOSPITAL AND COLLEGE.—The following scholarships have been awarded:—Senior Entrance Scholarship in Science (value £75): C. L. Pasricha, Caius College, Cambridge. Junior Entrance Scholarship in Science (value £100): B. M. Tracey, Monkton Combe School, Bath. Entrance Scholarship in Arts (value £100): J. Maxwell, Highgate School. Jeaffreson Exhibition (value £50): N. E. Laurence, Queen's Royal College, Trinidad.

CENTRAL SURGERIES IN BATTERSEA.—In order to release doctors of military age for service with the Forces the Local Medical War Committee, in conjunction with the Minister of National Service, proposes to establish central clinics in the metropolitan borough of Battersea. For this purpose the borough has been divided into three districts—east, south, and west—and practitioners have been appointed as organisers in each. In the southern district the centre proposed is the Bolingbroke Hospital, the governors having given their permission for the hospital to be used for the purpose. Six doctors have been nominated to take the evening surgery in rotation, and it is suggested that all panel lists should be pooled and the patients asked to attend at the centre instead of at the doctor's surgery. The London Insurance Committee have been asked to notify the insured persons of the proposed change. The number of practitioners on the panel in the three divisions referred to is 23, and the number of insured persons on their lists is 41,554, and the Committee, while realising that an emergency has arisen which must be met in some radical manner, find that the scheme involves a great change in the policy of administering the National Insurance Act, to which they cannot assent without further inquiry. This inquiry is now being conducted in close coöperation with the Local Panel Committee.

Appointments.

BOWHAY, ALBERT, M.D. Durh., L.R.C.P., M.R.C.S., D.P.H. Cantab., has been appointed Temporary Medical Officer for the Bere Ferrers District by the Tavistock (Devon) Board of Guardians.

PATTERSON, NORMAN, F.R.C.S., Throat, Nose, and Ear Specialist at the Willesden Municipal Hospital.

Vacancies.

For further information refer to the advertisement columns.

Barrow-in-Furness, North Lonsdale Hospital.—Second H.S. £250.
Bath, Royal Mineral Water Hospital.—Res. M.O.
Bolton Union, Townley's Auxiliary Military Hospital, Farnworth, near Bolton.—Female Asst. M.O. £300.
Bournemouth, Royal Victoria and West Hants Hospital.—Res. M.O. £400.
Bristol General Hospital.—Physician.
Bristol Royal Infirmary.—H.P. and H.S. £120.
Carlisle City, Maternity and Child Welfare.—Female Asst. M.O. £425.
Carlisle, Cumberland Infirmary.—Female H.P. £250.
Central London Ophthalmic Hospital, Judd-street, W.C.—H.S. £50.
Derby Mental Hospital.—Asst. M.O. £350.
Dorset County Council Education Committee.—School Dentist. £300.
Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £120.
Dumfries and Galloway Royal Infirmary.—Asst. H.S.
Great Northern Central Hospital, Holloway-road, N.—H.S. £100.
Hospital for Consumption and Diseases of the Chest, Brompton.—H.P. 30 guineas.
Huddersfield County Borough.—Female Asst. M.O.H. £400.
Kensington Board of Guardians' Institution, Marloes-road, W.—Sec. Asst. Res. M.O. £325.
Leamington Spa, Warneford, Leamington, and South Warwickshire General Hospital.—Second Res. M.O. £200.
Manchester, Ancoats Hospital.—H.P. £200.
Manchester Education Committee.—Two Temp. Asst. Sch. M.O. £400.
Manchester Royal Eye Hospital.—Sen. H.S. £150.
Manor House Orthopædic Hospital, Hampstead.—Res. M.O. £300.
Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Surgeon. £200.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Res. M.O. Also Jun. H.P.
Norwich, Norfolk and Norwich Hospital.—H.P., H.S., and Res. M.O. £400 each.
Nottingham General Hospital.—Female Cas. H.S. £250.
Plymouth, South Devon and East Cornwall Hospital.—M.O. for Venereal Diseases Department. £500.
Queen Mary's Hospital for the East End, Stratford, E.—Res. M.O. Also H.S.
Rhondda Urban District Council.—Dental Surgeon. £300.
Royal Free Hospital, Gray's Inn-road, W.C.—H.S. £50.
Royal Free Military Hospital, Gray's Inn-road, W.C.—Asst. Res. M.O. £250.
St. Pancras South Infirmary, Pancras-road, N.W.—Female Asst. M.O. £300. Or Female L.T. 7 gs. p.w.
Scottish Women's Hospitals.—Female Asst. M.O.'s for France and Greece. £300.
Sheffield Royal Infirmary.—Res. S.O. £200.
Stoke-on-Trent County Borough.—Asst. Tuberc. O. £400.
Swansea Hospital.—H.S. £250.
Wigan Infirmary.—Jun. H.S. £225. Also Surgical Dresser. £150
Winchester, Hampshire County Council.—Temp. Asst. M.O.H. £400.
York City.—Temp. Tuberc. O. £350.

Births, Marriages, and Deaths.

BIRTHS.

ALDERSON.—On Sept. 26th, at West Cross, Merstham, the wife of Captain G. G. Alderson, R.A.M.C., of a son.

MOBERLY.—On Sept. 8th, at "Chudleigh," Ewell-road, Surbiton, Surrey, the wife of Alan V. Moberly, M.R.C.S., L.R.C.P., of a son.

STRAHAN.—On August 30th, at Hong-Kong, the wife of Stuart Séguin Strahan, M.B., of a son.

MARRIAGES.

COOPER—MCKENDRICK.—On Sept. 25th, at Whippingham Church, Isle of Wight, Anthony Ashley Cooper, Temp. Capt., R.A.M.C., to Henrietta Learmont (Rita) McKendrick, fourth daughter of the late Walter McKendrick and Mrs. McKenrick, of "Runrog," Hagg-crescent, Johnstone, Renfrewshire.

LLOYD-WILLIAMS—INGLIS.—On Sept. 28th, at Corstorphine, Midlothian, Bertram Lloyd-Williams to Dr. Isabel Inglis.

DEATHS.

GERMAN.—Killed in action, on Sept. 18th, Major Hugh Bernard German, M.C., R.A.M.C., late Surgeon, Royal Navy, aged 38 years.

GRIFFITH.—On Sept. 24th, at the Homestead, The Colony, Lingfield, Surrey, Alfred Hume Griffith, M.D. Edin., D.P.H. Cantab., aged 43.

HOWARD.—Killed in action in East Africa, on Sept. 6th, Charles Reginald Howard, M.D. Cantab., Captain, R.A.M.C., attached King's African Rifles.

SHAW.—On Sept. 30th, in London, Sir Doyle Money Shaw, K.C.B., R.N., late Inspector-General of Hospitals and Fleets, in his 88th year.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths

Notes, Short Comments, and Answers to Correspondents.

THE RATAN TATA FOUNDATION FOR SOCIAL SCIENCE.

Sir Ratan Tata, whose death we recently recorded, was one of the comparatively rare rich men willing to endow research into poverty and destitution, without which radical (as against merely palliative) treatment of social disease is not possible. The Ratan Tata Foundation of the London School of Economics, under the guidance of two able sociologists, Professor L. T. Hobhouse and Professor E. J. Urwick, has conducted a series of investigations which have added greatly to our knowledge of social conditions and afford good examples of the newer methods in social study.

There are two chief differences between the economists of to-day and those of a past generation. In the first place, much less confidence is placed in long trains of deductive reasoning and there is a closer checking at every stage by observed facts. Thus, the older writers—Mill, for example—dogmatised that where work was undertaken to supplement the employment on which a family was mainly dependent a lower wage would be accepted than would be the case if the family had no other means of livelihood. The Ratan Tata Foundation, inquiring into the condition of the home workers in East London, found that the reverse was true. Of the women in the tailoring trade who worked to supplement their husband's wages one-half were being paid good rates; whilst of the women who were entirely dependent on their earnings only a quarter were well paid. The explanation was that the latter dared not stop their work, whilst the former could do so "at a pinch," and therefore stood out for better money.

The second mark of the newer school of economists is that they pay much more attention to the psychology of industrial conditions. Ruskin long ago warned his contemporaries that many of their deductions were valueless because they had posited a non-existent "economic man." Mr. R. H. Tawney, who has written for the Ratan Tata Foundation two monographs on the working of the Trades Boards Act, expresses the truth very neatly: "Economic processes are not reducible to sums in simple arithmetic. The reaction which follows an increase or reduction in wages is not merely quantitative but qualitative ..... The consequences are comparable to the effect not of mechanical stresses, but of chemical reactions. There is more in the result than appears in the components, an unknown factor whose operation defies deductive reason." He illustrates this by a large body of testimony from employers that higher wages often mean better output and therefore lower cost of production. "To be well paid gives the workers dignity and self-respect. They *think* they are worth more, and therefore they are worth more."

Such investigations and publications as those of the Ratan Tata Foundation are introducing a new and sounder social science.

PARAFFIN THERAPY.

MELTED paraffin has a lower specific heat capacity than that of water—roughly, about one half, and lower for the harder paraffins—and can hence be applied to the body at a higher temperature. It also shrinks as it cools, and so makes a slight equal pressure on the tissues beneath. These characters give it advantage in the treatment of swellings and stiffness of joints, which are thus treated by it in St. Anne Hospital at Toulon, as we are told in the *Archives de Médecine Navale* for August. This use of paraffin (paraffitherapy) has been adopted by the French Admiralty. It was introduced by Dr. Barthe de Sandfort, who also introduced ambrine for the treatment of burns, and was formerly a medical officer in the French Navy. There is a room in that hospital for this treatment. A large tank of melted paraffin is the central feature. In it are two coils, one (steam) for raising the temperature to 120° C. (248° F.) to sterilise it, the other (cold water) to reduce its temperature to the practical limit of 53°–50° C.) (127°–122° F.). The melted paraffin is either put into baths in which is immersed so much of the patient as is necessary, or the patient being laid on a sheet, the hot liquid is poured over him by jugs or ladles. A patient with a stiff knee, for example, will every day for the first week have his knee dipped in a bath and removed, dipped a minute later and removed, until his leg is encased in paraffin, when he rests for half an hour or so and has his paraffin case removed, as is easily done, the case being separated by the free sweating which occurs. After the first week the treatments come every second day, and at the end of a fortnight his knee should be well—that is the usual experience. Heat somewhat prolonged, equable pressure, sweating—these are the factors which are supposed to account for the so frequently successful results. The diseases treated are swellings, stiffnesses, contractions of joints and fibrous ankyloses; neuritis, phlebitis, neuralgias, and arthritis, whether gonococcal, gouty, or rheumatic, and whether acute, subacute, or chronic. The treatment does not exhaust the patient, but increases his appetite, and the paraffin, constantly sterilised, is but little wasted. The *Archives de Médecine Navale*, from which we quote, reports this treatment as a definite therapeutic advance.

THE ZEEBRUGGE MOLE.

WE have received from Messrs. Pain and Co., 17, Farringdon-avenue, London, E.C., a copy of a little poem by Mr. Sydney Lee entitled "Well Done, *Vindictive!*" and celebrating the raid on Zeebrugge on the eve of St. George's Day of this year. The poem is a picturesque and vigorous piece of verse, the "doggerel" style being reminiscent of the old chanty. The closing verse illustrates the rough directness of the author:—

> "Now Britons! when you wish to stir the blood within your veins,
> Just chuck all thoughts of business, your losses and your gains,
> And remember the *Vindictive*, and tell the boys around
> Of those deeds of British valour that made the World resound."

The poem is published at the price of 6*d.* for the benefit of King George's Fund for Sailors.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.1.
MEETING OF SECTION.
Thursday, Oct. 10th.

NEUROLOGY (Hon. Secretaries—C. M. Hinds Howell, E. G. Fearnsides): at 8.30 P.M.
Discussion:
A Discussion will be opened by Dr. Wilfred Harris on "Causalgia, and its Treatment."

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.
THURSDAY, Oct. 10th.—5 P.M., Chesterfield Lecture:—Dr. M. Dockrell:—Eczema in all its Stages.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.
Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—
WEDNESDAY, Oct. 9th.—4 P.M., Prof. A. Keith: Anthropometry and National Health.

Communications, Letters, &c., to the Editor have been received from—

B.—Mr. J. Burns, Edinburgh; Dr. C. Burland, Liverpool; Capt. W. G. Ball, R.A.M.C.(T.); Capitano Medico Prof. Dr. G. Breccia; Major-Gen. Sir David Bruce, K.C.B.; British Fire Prevention Committee, Lond.; Board of Agriculture and Fisheries, Lond.

C.—Capt. J. Campbell, R.A.M.C.; Dr. J. R. T. Conner, Lond.; Mr. A. L. Clarke, Hastings; Chicago School of Sanitary Instruction; Mr. F. R. Cave, Okehampton; Capt. J. C. Clayton, R.A.M.C.; Major H. A. Cookson, R.A.M.C.(T.)

D.—Dr. L. Doncaster, Cambridge; Mr. A. C. J. Dalby, Avonmouth; Dr. A. B. Dunne, Doncaster; Dept. of Scientific and Industrial Research, Lond.; Dr. S. Davies, Woolwich; Capt. S. C. Dyke, R.A.M.C.

E.—Dr. A. B. Elliott, Abergele; Dr. F. W. Edridge-Green, Lond.

F.—Major M. Foster, R.A.M.C.(T.)

G.—Mr. J. W. G. Grant, Lond.; Dr. J. Gairdner, Crieff.

H.—Dr. J. S. Haldane, Oxford; Prof. W. Hall, Bristol; Capt. R. Hall, R.A.F.; Mr. J. T. Henderson, Pietermaritzburg.

I.—Insurance Committee for the County of London.

K.—Kensington, Medical Officer of Health of.

L.—Dr. H. Lyon-Smith, Lond.; Mr. S. M. Lawrence, Gravesend; Mr. E. M. Little, Lond.; Local Government Board and Scottish Office, Lond.; Mr. A. H. Long, Lond.; The Library Press, Ltd., Lond., Director of; London Units of the Scottish Women's Hospitals for Home and Foreign Service.

The Treatment OF GUNSHOT WOUNDS OF THE JOINTS.

BY J. CAMPBELL, M.D. LIVERP.,
CAPTAIN, R.A.M.C. (S.R.); LATE SURGICAL REGISTRAR, ROYAL INFIRMARY, LIVERPOOL; SENIOR ASSISTANT TO THE PROFESSOR OF ANATOMY, ROYAL COLLEGE OF SURGEONS IN IRELAND, ETC.

PART I.

GUNSHOT wounds involving joints form something like 4 per cent. of the total number of wounds met with in the present war. They are of first-rate importance owing to the frequency with which they are followed by loss of life or limb or, short of these, by ankylosis, complete or incomplete, with a corresponding degree of incapacity to the individual.

This paper is founded on an experience of over 800 cases and on operative and post-operative treatment carried out in casualty clearing stations and general hospitals. Amongst those treated in the latter, separate series of cases involving the various joints were isolated and collected and not discharged to England till either completely healed or sufficiently far advanced in the process of healing to place them beyond any likelihood of subsequent interference, and this was verified by tracing the later history of all such cases to their termination in England. In a fair percentage of the remaining cases the end results were obtained by information gained from England. In this way I venture to think that some definite conclusions can be drawn as to the merits of the various methods of treatment and as to those most worthy of adoption.

CHARACTERISTICS OF JOINTS.

Synovial membrane.—Most joints are lined by synovial membrane. This possesses, in common with other serous membranes, two important characteristics on which all successful treatment is based—namely, (1) an extraordinarily strong capacity for overcoming septic infection; and (2) an equally strong capacity for forming adhesions. These adhesions form with considerable readiness; at the end of 24 hours they are very well marked indeed; sometimes they may form within several hours. As a result of this capacity for forming adhesions the advent of sepsis from without is largely prevented, and any sepsis inside the joint remains localised for a considerable time, granted that the exudation poured out has a free exit. It is largely in consequence of these two characteristics that joint lesions are now regarded as of much less surgical importance than was thought to be the case several years ago, granted that the wound is efficiently treated within a reasonable time of its infliction.

Articular cartilage.—Articular cartilage depends for its existence upon lymph. Anything, therefore, which interferes with its normal supply will assist in causing its death. Intact cartilage presents a definite resistance to infection and does not readily undergo erosion in the presence of sepsis, if it is not at the same time the subject of pressure. On the other hand, if it is the subject of pressure it does rapidly undergo erosion at the site of pressure. This is an important consideration in treatment and shows the necessity for maintaining constant extension in the axis of the limb so as to minimise or abolish the pressure of opposed cartilaginous surfaces on one another. Granted this is efficiently maintained, erosion can be largely avoided or its onset delayed in the presence of low or even moderate degrees of sepsis.

This influence of pressure on erosion was very vividly impressed on me in a case of low grade infection of the knee-joint resulting from secondary spread from a foreign body in the immediate neighbourhood. The case came under my care somewhat late (about two and a half to three weeks after the onset of the arthritis) and at the time was not making satisfactory progress; there was a definite degree of outward flexion causing deformity; extension had been more or less satisfactorily maintained on a Thomas's knee-splint. Radiographs taken at the time showed considerable erosion and loss of outline of the cartilage over the external condyles of femur and tibia, with no observable change over the internal ones.

The differences between the two sides of the joint were so striking as to induce one to make inquiries as to the details of the previous treatment. It transpired that it had been the custom to turn the patient over on to his normal side when changing the dressings and attending to the skin over his back. As a result the limb tended to sag inwards during the process owing to stretching of the joint capsule and ligaments from inflammatory softening which always accompanies an arthritis; consequently, the external condylar surfaces were jammed together and the internal ones separated, producing the condition described above.

The onset of erosion is frequently associated with "night starts." When these make their appearance it is a sure index of imperfect extension, and they disappear immediately the extension is tightened up and made adequate.

Arrangement of the blood-supply.—Another point of the greatest importance is the arrangement of the blood-supply to the articular ends of the bones; and as these are covered by avascular cartilage it follows that in gunshot wounds large masses of bone may readily be completely cut off from their vascular supply. Especially is this the case with the head of the femur when the wound involves the intracapsular portion of the neck of the bone. The same applies, only to a less extent, in the case of the head of the humerus and in varying degrees to the ends of other bones. These masses of loose bone form a suitable nidus for the growth of any organisms that have found their way into the wound, and are then often the site of origin of an acute arthritis.

Structure of the articular ends of bones.—The epiphyses and adjacent parts of the shaft are formed of cancellous tissue. Like other tissues—e.g., muscle, this suffers contusion, and then becomes just as liable to septic invasion with its attendant dangers. Contused cancellous tissue, then, must play a large part in producing septic arthritis in many cases.

GENERAL CONSIDERATIONS GOVERNING TREATMENT.

The general factors governing treatment cover a wide range and involve considerations of: (1) the patient; (2) the surgeon; (3) surrounding conditions generally; (4) nature of wound; (5) time elapsed after being wounded; (6) nature of infecting organism; and (7) radiography.

The Patient.

As regards the patient himself, the following should be taken into consideration:—

Age.—The younger the patient the more readily is he able to withstand conservative measures.

General condition.—The better this is, the more does the above suggestion apply. It is well when resorting to conservative measures in cases involving the larger joints, especially the knee and hip, to keep a close eye on the patient's general condition, for sometimes the local condition may appear to be making satisfactory progress, yet the patient is slowly going downhill and the pulse beginning to lose its volume. When this event occurs the time has passed for persistence in conservative measures, and the limb must be sacrificed.

Multiple wounds.—The more wounds a patient has, the less should be the degree of effort in the line of conservatism. For instance, if a patient is injured in such a way that the upper and lower limbs are both in jeopardy, unless there is reasonable certainty of saving both it is better to save the upper at the expense of the lower, sacrificing the leg at the outset rather than lose both arm and leg and, maybe, the life of the patient later on.

Occupation.—It is well to ascertain this at the outset, first, because in certain work a rigidly stiff limb is less useful to some patients than an artificial one; and, secondly, because it gives guidance as to the best position in which ankylosis should be secured, if such is likely to ensue—e.g., a farm labourer should have the elbow ankylosed at an angle of 135° to allow of the lifting of heavy weights; a professional man at an angle of 100°, to allow of writing and of access to the pockets. The same applies to the shoulder: the heavier the work done the less should the arm be abducted from the side (but in no case less than 40°), and the lighter the work done and the more mobility required for the arm the nearer an abduction of 90° should be secured. Other injuries will also largely affect the position for ankylosis—e.g., if the other hand be lost, then the remaining arm must be secured so that the patient can feed himself—that is to say, in complete flexion with semi-pronation of the forearm.

The Surgeon.

In serious cases treatment largely depends on the surgeon himself. If his skill and experience are large he naturally has the right to attempt greater degrees of conservatism than if his experience is small. His speed in operation and the amount of time he has at his disposal to give to after-treatment are also important. In doubtful cases nothing is more to be regretted than division of responsibility for treatment during the time when risk to life or limb is present.

Surrounding General Conditions.

During times of stress it is only natural that less conservative treatment should be adopted than during quiet periods on account of the lack of time at the disposal of everyone generally to attend to after-treatment, and also on account of the urgency of many other cases awaiting operation, for conservative measures take up considerably more time than more radical ones.

Nature of the Wound.

This is a matter of first-rate importance and involves consideration of: (*a*) size of aperture of entry or exit or both; (*b*) nature of the missile; (*c*) extent of the bone injury.

(*a*) *Size of entry or exit or both.*—The size of these apertures largely determines the treatment required—e.g., leech-bite entry and exit are usually not followed by sepsis, even when accompanied by severe fracture. Large wounds, on the other hand, even with little if any bone injury, are vastly more important in that their size varies directly with the amount of septic material that was introduced into the joint by the missile, and also with the amount of sepsis that has subsequently invaded it from without. Large external wounds, however, that communicate freely with the synovial cavity and thereby allow of the free exit of fluid from it, are appreciably less dangerous than similar wounds with valve-like openings which do not allow of this escape. With the former type I have frequently seen but little bad result in knee-joints, but with the latter very frequently serious consequences. In the one case the sepsis became localised by synovial adhesions; in the other it was soon disseminated over the entire joint surface by exudate. Unoperated cases demonstrating these differences in results were frequently to be seen in the general hospitals in 1915 and 1916.

(*b*) *The nature of the missile* largely determines the urgency or otherwise of the case; shell wounds are much more dangerous than those caused by undistorted rifle or machine-gun bullet. Indeed, early in the war it was comparatively uncommon in the base hospitals to see bad after-results accrue from the latter, granted that the ingress of sepsis from without was prevented, even in the case of quite large exit wounds. Where, however, the entry wound was large the cases had almost equally as much sepsis along their track and were equally as dangerous as shell wounds.

The size of the missile has an important bearing on the liability to sepsis and the urgency or otherwise of the necessity for intervention. It can be laid down as a working rule of practical importance for use in times of stress that missiles up to the size of a small pea usually give but little trouble; hence if such cannot be operated on within 48-60 hours, they are usually best left alone until all danger of lighting up sepsis by operation has passed. It follows, too, that these may, with a fair degree of safety, be allowed to pass straight to the base, after being efficiently immobilised.

Retained foreign bodies.—The relation of these to radiography will be discussed later on. There is no doubt that the sooner they are removed the less is the risk to the patient. The most satisfactory treatment is to excise the wound if possible *en masse*, together with the foreign body, at as early a time as possible; the joint is then carefully washed out, and the wound closed in layers—the synovial membrane by a continuous fine catgut suture to ensure a watertight closure, the capsule, muscle, and fasciæ in their separate layers by interrupted sutures, and finally the skin by silkworm gut.

In the absence of adequate and efficient radiographic reports (and perhaps even with the aid of them) the wound may require to be excised in layers. Any damaged bone surface is then carefully gouged or chiselled away *en masse*, and the joint cavity irrigated as before. The damaged surface of bone is then very lightly smeared with B.I.P. paste, and the joint closed as before.

It is surprising how long the effusion into a joint will remain sterile in cases where the foreign body is retained, especially if the limb is immobilised. In the case of the knee-joint, as late as the second, or even the third, day, I have on a number of occasions found the fluid sterile on cultivation with quite a large shell fragment *in situ*, even with fragments of clothing adherent to it—yet the foreign body readily yielded heavy cultures.

(*c*) *Extent of bone injury.*—This is a factor of paramount importance in treatment, and assumes a rôle of increasing prominence the greater the time that has elapsed between the injury and the operation. If the case is one due to rifle or machine-gun bullet with small entry and exit, however much the extent of bone comminution, there is little doubt but that the case is best left alone, excising perhaps the wounds in the skin only. Whatever the missile, if the case is seen early and has ragged entry and exit wounds, and more especially if the missile be retained, primary suture after efficient excision of the wounds and removal of all loose bone is the best line of treatment to adopt if it be feasible. Short of this, only two courses are left open as a primary measure—excision of the joint and amputation. Which of these should be adopted depends on the ability or not of being able to retain the case in hospital after operation and the patient's general condition. In certain cases the danger of accompanying fracture can be largely, if not completely, abolished by isolating the bone lesion from the synovial cavity; this may be accomplished by suturing together opposed synovial surfaces round about the fracture or by transplanting flaps of the same. This can sometimes be accomplished with ease in the knee-joint.

A serious and difficult problem that confronts the surgeon when operating on these cases is the amount of bone that should be removed.

It has been mentioned above that the cancellous tissue near a joint is very liable to contusion with its resultant dangers, particularly sepsis. Indeed, in the general hospitals it used to be quite common to see necrotic patches of this cancellous tissue on the cut surface of any bone in excised joints and in other cases also. This was largely due to the fact that sufficient of the contused tissue had not been removed.

It is advisable in these cases to make a point of removing contused tissue till definitely oozing bone is exposed with the chisel. This does not necessitate removal of all the contused bone any more than, in the case of muscle wounds, all contused muscle should be excised; otherwise far too much tissue would be unnecessarily sacrificed. If this hopelessly damaged bone is not removed any organisms remaining behind are liable to produce not only local sepsis with its serious consequences, but even a fulminating osteomyelitis. This last complication was not infrequently seen at the base in the earlier part of the war, when so many cases arrived there without any operation having been previously performed. Its presence is suggested by the patient's serious general condition and by tenderness, possibly with thickening along the entire length of the bone. On amputation its presence can usually be readily recognised in the marrow.

If the case has become septic before the operation is resorted to, more radical methods must be used varying, according to the joint involved, from drainage (e.g., elbow) to excision (e.g., hip, shoulder) or even amputation.

Fractures secondarily involving a joint.—Such cases treated early—i.e., within six to eight hours or even longer—usually yield satisfactory results if the wound and fracture are treated locally and the crack left severely alone. Should the joint be distended with bloody effusion it is well to empty it and then apply a firm bandage to prevent its recurrence. Later on, when sepsis may have spread along the entire extent of the fracture, a certain number settle down readily, granted that the fracture is well drained and carefully immobilised. But unfortunately the joint has often to be drained as well, or even the limb sacrificed in the case of the larger articulations.

Time Elapsed after Receipt of Wound.

This must be ascertained at the outset, before operation, as it is of more importance in some respects, in the case of joint wounds, than in the case of other wounds of the extremities. On it depends, in a way, the type of operation that must be done. Roughly speaking, there are two types of cases—those under 24 and those over 36 to 48 hours old. This division is entirely arbitrary; the intermediate cases cannot be readily classified, but must be treated on their merits according as they appear to belong to the first or second group.

Cases over 36 or 48 hours old are best left alone if progressing not unsatisfactorily after having the skin in the neighbourhood carefully cleaned and sterilised and the joint immobilised, this being aided by fixed extension in the straight position. With regard to cases that have been mounted in flexion after being hit, it is well to remember that the advantages to be gained by fixed extension may be outbalanced by the consequences of moving a joint that is settling down. Such movement may break down the synovial adhesions which form the only existing barrier that prevents external sepsis from invading the joint.

Cases under 24 hours old are, as a whole, best operated on immediately and the wounds closed. In a number of cases with marked damage to the neighbouring tissues or in which the wound cannot be excised perfectly, it is advisable to close only the joint cavity and capsule. The rest of the wound is left widely open but with loose sutures placed *in situ* ready to be tightened up later on. The wound is then well packed with paraffin gauze, tightly bandaged, and left undressed for 2-4 days, when, granted it is sufficiently clean bacteriologically, the wound is closed by tightening the stitches. Should the condition be not then satisfactory, it is advantageous to apply the Carrel-Dakin method of treatment if this has not already been used from the outset.

Nature of the Infecting Organism.

As elsewhere, different organisms and different strains of the same organism produce widely different effects and in later cases treatment may depend on their recognition. Those most frequently encountered and clinically the most important are: (*a*) The bacilli of gas gangrene; (*b*) staphylococcus; (*c*) streptococcus. Of these the most dangerous to life and limb is the *streptococcus*, but even here the strain is largely the governing factor—e.g., a highly hæmolytic one infecting the knee-joint gives rise to a fulminating septicæmia, fatal within a few hours; on the other hand, quite a large number infected with other strains readily settle down.

As regards infection with *staphylococcus*, most cases get well if carefully immobilised, the source of infection, if

possible, removed, and cross infection from without prevented. Nearly all more serious staphylococcic cases that do not respond to the above treatment settle down after efficient and suitable arthrotomy followed by drainage.

B. perfringens, when invading a joint cavity, has a strong tendency to disappear; but it is, unfortunately, almost invariably accompanied by either one or both of the above organisms. It is these others that assume the major importance in treatment. In this connexion one should mention that the presence of gas in a joint does not necessarily indicate *B. perfringens* infection; it is sometimes due to certain strains of streptococci.

Estimation of the degree of infection.—This is by no means an easy matter to decide and requires a large clinical experience to enable one to draw reliable conclusions, and even then errors are not rare—i.e., granted that efficient conservative measures are adopted. Clinically, the degree of sepsis is best estimated by the pulse-rate and general appearance rather than by the temperature. It has been my custom not to worry about any case in which the pulse-rate has been below 100, whatever the temperature might be. A high pulse-rate, more especially when associated with a rising temperature, and still more so with a dry tongue, is of serious omen. But even in these cases it is well to proceed to a bacteriological examination of the joint contents before resorting to drastic measures, because occasionally in such cases one is unable to obtain cultures of organisms and the case settles down on being left severely alone. Some complication perhaps is the cause of the condition.

Besides the above, other methods of estimating the degree of infection should be followed out—namely: (*a*) cytological, and (*b*) cultural.

The cytological examination of the exudate yields information in regard to the nature, number, relative proportion, and staining characteristics of the cells present. A relative increase in the number of organisms to leucocytes suggests unsatisfactory progress, and the converse holds equally true.

Nature of the cells.—An exudate showing a high proportion of mononucleated, and more especially eosinophile cells, indicates a mild degree of infection as compared with one in which they are few or absent.

Number.—The fewer the leucocytes and the more the organisms, the more dangerous is the infection as a rule, and vice versa.

Staining characteristics.—Cells staining badly and showing much disintegration indicate either (*a*) cytolysis due to toxins, or (*b*) senile degeneration. The general appearance of the cells and the high proportion of lymphocytes and eosinophiles present in effusions of some duration readily allow of differentiation of the two types.

The cultural characteristics of the organisms are of value, especially in the case of the streptococci as demonstrated by the degree of hæmolysis they may produce; the higher the hæmolytic power the graver is the infection. Infection of the knee- or hip-joints with strongly hæmolytic streptococci is remarkably and rapidly fatal, usually from a fulminating septicæmia.

Notwithstanding, however, the value of these laboratory findings, one must always bear in mind the general condition of the patient.

If the patient is slowly going downhill, some modification of the treatment is required. In doubtful cases nothing gives a better idea of a patient's condition than his general appearance and the changes it undergoes. These changes are not readily appreciated by one in constant attendance on the patient, but are painfully obvious to anyone seeing him at intervals (2–4 days, for example). Indeed, in such cases an outside opinion on this point every 2–4 days is a useful and necessary adjunct to treatment, and may be the means of avoiding some unfortunate results.

In this connexion there is one source of error which, unless it is appreciated, is fraught with serious consequences: when the septic exudate, after being under high tension for a time, bursts through the capsule, there is an appreciable improvement in the general condition, the pain locally is less, and the temperature and pulse-rates fall appreciably, due to diminished toxin absorption from lowered tension. But this improvement is only temporary; at the end of 2–3 days the patient's condition is as bad as, if not worse than, before. The bursting of the infection through the capsule is readily seen by the local increase in swelling, not confined to the limits of the synovial cavity. Such a condition calls for immediate interference, otherwise extensive tracking along fascial planes may occur, with its attendant dangers.

Radiography.

The value of efficient radiographic examinations in joint cases cannot be over-estimated. To be adequate it entails: (*a*) Localisation of any foreign body present by marks on both surfaces of the limb in two planes at right angles to one another, and (*b*) good radiographs, taken by preference in two planes as before. In each instance the most suitable planes for use are the anatomical antero-posterior and transverse ones. I think that such an examination yields more information and is of vastly greater value than one made by stereoscopic plates alone.

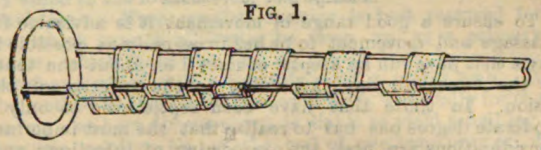
Granted that the examination has been carried out as described, an accurate estimation of the site of any foreign body and the extent of bone damage can be readily made; and in consequence the nature and site of operation can be planned from the outset, so as to allow of excision of the wound in an efficient manner—perhaps in one piece, inclusive of the foreign body.

FUNDAMENTAL PRINCIPLES UNDERLYING TREATMENT AND OPERATIVE TECHNIQUE.

Absolute Rest and Fixation.

Absolute rest and fixation are the essential principles underlying the successful treatment of all joint wounds in their early stages, and their value cannot be over-estimated. Cases have frequently been sent under my care which appeared to be doing unsatisfactorily, but which completely settled down after securing adequate rest and fixation combined with efficient extension, and I am quite convinced that a large number of such cases escaped serious surgical interference and even amputation merely by securing these fundamentals. The best method for securing them, whether for transport or treatment, is by fixed axial extension of the limb in one of Thomas's or Jones's splints, the limbs being supported in it by bands of perforated zinc, the ends of which are turned round the lateral bars (Fig. 1);

FIG. 1.



finally, the limb is well padded, covered with Gooch's splinting, and secured in the splint by a firm bandage. *To ensure an absence of movement during dressings it is essential for as few as possible of the metal supports to be removed, and then only with the greatest care. No movement, however slight, should be permitted.* On not a few occasions have I seen limbs and even lives jeopardised by careless movement of a large joint during a dressing.

In this connexion the use of strips of flannel or cotton bandage to support the limb cannot be too strongly condemned; they are not rigid, and so permit of an appreciable amount of movement in bed and during transport—sufficient to vitiate the result in many of the more serious cases.

The need for rest and fixation by no means begins in the C.C.S.; it is essential for them to be secured at the time the patient is wounded or at the next earliest moment possible. Since splints—more especially the Thomas for knee cases—have been used systematically at the regimental aid-post or field ambulance the results obtained in wounds of the joints have considerably improved. But even yet it is surprising how many cases escape having splints applied before reaching a C.C.S., and still more surprising how common it is to see the Thomas's knee-splint imperfectly applied.

In one's own experience fully 40–50 per cent. reach the C.C.S. with the extension bands quite slack; this is nearly always due to the bands being tightened before the ring of the splint has been pushed home against the ischial tuberosity; in such a case, seemingly adequate extension has been applied at the time of splinting, but the point of counter extension has really been the fleshy fold of the buttock assisted by the weight of the patient, and not the non-yielding tuberosity of the ischium. To avoid this, it is essential during the application of the splint to pull down through the ring this fleshy mass—otherwise the splint cannot rest against the bony point.

Another cause of imperfect extension is the use of a Thomas's splint with a ring that is either too large or too thickly padded—though when applied it may rest against the bone, it slides inwards on to the perineum with the slightest movement, and so extension is lost. This defect may generally be surmounted by placing a *large, firm* pad between the outer part of the ring and the hip; thereby any inward displacement is prevented.

A similar criticism applies to the use of a Thomas's arm-splint fitted with a swivel attachment—it certainly does permit of easier transport by allowing adduction of the limb, but only at the expense of loss of extension and fixation.

Plaster-of-Paris is sometimes used instead of splints to secure fixation—in late stages of convalescence it is useful to allow of the patient getting about. But in early septic cases its use is attended with many disadvantages. Chiefest of all is the impossibility of preventing the plaster from becoming soiled with the septic discharge from the wound; this then forms a centre from which the wound is constantly reinfected. Another important disadvantage is that it does not allow of access to the adjacent parts of the limb, thereby preventing all possibility of massage and obscuring any changes in the neighbourhood of the joint.

Asepsis.

It is essential for this to be secured at the time of operation. There should be one or several changes of the instruments employed. After excision of the wound locally down

to, and inclusive of, the capsule it is advisable to begin again as for an entirely fresh operation. This should include covering up of the excised wound, re-sterilisation of the limb, and a fresh incision to open the joint in an entirely different situation. Asepsis, too, is just as important at each subsequent dressing and cannot be too strongly insisted on. In the writer's opinion, joint cases should in each unit be allocated as far as possible to special wards and tended by persons skilled in their treatment and in asepsis.

Dressings should be changed as infrequently as possible for two reasons: (1) the risk of movement, and (2) the risk of fresh infection from without. This latter is a consideration of prime importance where it has been impossible to close the joint cavity and sew up the wound. For these cases it seems best to use B.I.P. paste in preference to any other method of wound treatment, even the Carrel Dakin one. In the treatment of individual cases division of responsibility as regards dressings is to be deplored; the dressings should be undertaken by the same person on each occasion.

Massage and Movement.

To ensure a good range of movement it is advisable for massage and movement to be begun as early as possible in cases that have run an aseptic course—i.e., about the tenth to the twentieth day, according to the severity of the lesion. In those that have been septic even to only a moderate degree one has to realise that the most important considerations are, first, the overcoming of infection; and, second, the avoidance of a recrudescence, and nothing is more prone to cause the latter than too early movement. Such cases should have been free from all clinical signs of infection for at least three weeks or even longer, according to the degree of sepsis, before movement is resorted to. The appearance of effusion in the joint or of general or local reaction after movement is an indication for a pause in its application. The resumption of movement in joints where foreign bodies are retained is liable to be attended by trouble that may quite easily cost the patient his limb. Unless the foreign body is removed by operation, movement is best postponed for at least several months.

Use of the Tourniquet at Operations.

The application of a tourniquet to the limb prior to operation is essential if a uniformly high standard of results is to be obtained, for several reasons:—

1. The spread of sepsis by contaminated blood flowing over freshly cut aseptic surfaces is avoided.
2. The need for using many instruments is diminished.
3. The field of operation is not obscured by blood.
4. Ligatures need but rarely be used, and hence their action as foreign bodies is avoided.
5. All bleeding into the joint cavity is prevented, not only at the time of operation but subsequently, granted that the limb is very firmly bandaged and completely immobilised in the splint before the tourniquet is removed. I am quite sure that one cause of failure in a number of cases where the tourniquet is not used (especially knee and tarsal ones) is due to the extravasation of blood into the joint cavity after the bandage has been removed. The clot so formed provides a suitable nidus for organisms to multiply in and prevents opposed synovial surfaces from forming adhesions and thereby localising sepsis.

Washing Out of the Joint Cavity.

As a routine measure at a primary operation where the joint is laid open this appears useful.

From personal experience it is best carried out either with a solution in water of 2 per cent. di-chloramine-T and 2 per cent. neutral sodium oleate or with a mixture of hydrogen peroxide and Dakin's solution. At the same time flakes of fibrin and fragments of blood clot should be removed individually and with the greatest care by forceps. Each of the mixtures mentioned above is of benefit from its mechanical rather than its antiseptic action. When used for septic arthritis care should be taken that adhesions are not broken down by pressure; otherwise recesses that are locked off may have sepsis driven into them.

After drainage of the joint cavity it was the rule earlier in the campaign to wash out the joint at each dressing; the result of this was that adhesions were prevented from forming or were broken down whilst still feeble. In this way the joint cavity remained widely open and was only slowly obliterated. Meanwhile it was exposed to and not infrequently became the subject of cross infection with its increased dangers. There is no doubt that such irrigation is a frequent cause of failure, and should not be adopted. Its abandonment as a routine measure has enormously improved results, especially in knee cases.

Obliteration of Dead Space: Use of Paraffinised Gauze Packs.

Accumulations of blood are liable to occur in wound recesses after operation, and may then be the starting-point of septic infection—the blood acting as a dead tissue in which organisms left behind after operation can flourish. Every attempt, then, should be made when dealing with early wounds to prevent these accumulations by obliterating all "dead space" and yet allow of drainage of any exudate that may take place.

If primary suture is performed, this may be accomplished by careful hæmostasis, followed by the application of a very firm bandage. Should, however, the wound be unsuitable for primary suture or, with suture, still show a dead space, these objects can be gained by using as a pack gauze soaked in sterilised liquid paraffin; this is carefully and firmly pushed into every recess and the limb firmly bandaged. The pack exerts pressure, and so helps in hæmostasis, and the paraffin hinders coagulation of blood and serum, and so allows of their drainage along the gauze into the more superficial parts of the dressing. Such a pack may be left *in situ* for two to four days or longer, the superficial parts of the dressing being changed on the first or second day only if the "dressing has come through." When the pack is removed it may be replaced by paraffinised or dry gauze as required, unless the wound can be entirely closed.

The cases in which this treatment yields excellent results are those showing large loss of bone substance involving articular cartilage, and in which the synovial cavity cannot be closed for anatomical reasons. Such cases are universally acknowledged to be amongst the most difficult of all to treat satisfactorily. I always prefer to use the paraffinised gauze in conjunction with a small amount of B.I.P. paste.

Moist gauze when used to obliterate dead space does not yield anything like so good a result. It is inadvisable to use it after removal of a paraffin pack. I have been greatly impressed, particularly during the past ten months, by the readiness with which gunshot wounds, after excision, may be successfully sewn up by primary or delayed primary suture if all moisture is very carefully kept away from them. On the other hand, if moist gauze is used as a primary dressing or to replace any paraffinised pack, a much larger percentage of excised wounds either do not reach a condition suitable for such measures or if sutured break down. This is due to the moisture providing a suitable medium for the growth of organisms.

Herein, I think, lies another advantage to be gained by the use of paraffinised gauze. To sum up its chief advantages, one may say it allows of better drainage of the wound than can be obtained by the use of moist dressings without possessing their disadvantages. It does not furnish a moist medium in which organisms can flourish; it does not adhere to the surface of newly forming granulations, and on removal does not cause bleeding, as does dry gauze; thereby the risk of opening fresh paths for septic invasion is avoided.

Unless the wound has been excised *en masse* the use of fat grafts to obliterate dead space would seem to be not unattended by risk. Where, however, asepsis can be reasonably guaranteed they yield excellent results. Should any gap be left in an articular surface, one way of obliterating it that yields useful results is to fill it up with a 2 per cent. paste of di-chloramine-T in neutral sodium oleate or neutral sodium stearate before closing the joint. A mass of B.I.P. paste should not be used owing to the risk of bismuth poisoning arising shortly afterwards or from the danger of its acting as a foreign body and being extruded later on.

Secondary Operations.

In a base hospital these are not infrequently required for one reason or another. It is essential to carry them out without removing the splint. To attempt otherwise courts disaster from a recrudescence of septic arthritis with its attendant consequences. Careless manipulation or movement in septic infections affecting a large joint may rapidly sweep off a patient from a fulminating septicæmia.

OPERATIVE TREATMENT.

Besides the essentials in treatment described above certain other methods are used and may be discussed at once.

Aspiration.

This procedure is useful in doubtfully infected cases for the purpose of making bacteriological and cytological examinations of the joint fluid, but if carelessly performed the damage done to the articular cartilage and synovial lining may immeasurably outweigh the advantages gained. It is advisable to use it as rarely as possible in those cases that are but mildly septic; indeed, here it is scarcely necessary, since the ordinary clinical signs yield information of more practical value for treatment. It is necessary, however, when the intra-articular tension becomes high, otherwise the infection may burst outside the synovial cavity and perhaps track widely along the fascial planes.

Exploration and Washing Out of the Joint Cavity followed by Suture.

This procedure appears to have but a limited application. Indeed, the greater one's experience is in dealing with infected joints the less does one resort to this procedure, for two reasons: first, because such cases as seem suitable for the treatment almost invariably settle down if carefully

immobilised in the extended position and left severely alone, aided perhaps by aspiration; and, secondly, because in those cases where it is used further operative procedures have nearly always to be resorted to.

As regards the earlier cases in which this treatment was used and which seemed to derive benefit from it, looking back on them one cannot but be impressed by the fact that almost all would have made equally satisfactory, if not better, progress had they been left alone.

Should this procedure be adopted, free exit for the fluid should be permitted for fear lest any recesses in the joint cavity that are already locked off by adhesions should be opened up and have sepsis driven into them. All flakes of blood clot, fibrin, and pus should be carefully sought out and removed; finally, the limb is bandaged tightly to prevent exudation and allow of the rapid formation of adhesions.

Excision of the wound has already been discussed above.

The Use of B.I.P. Paste.

The value of Morison's B.I.P. paste in wound treatment would appear to be completely established.

In regard to *early* joint cases it seems to have two valuable fields of use.

(*a*) In cases where a portion of the bone inside the joint has been chiselled away it is advisable to smear a small quantity over the freshly cut surface prior to closing the joint. Should a cavity of any sort remain in the bone connected with the joint it may be obliterated, as described above, with chloramine paste or a fat graft.

(*b*) In cases—e.g., the knee—where, after operation, a large gap that cannot be repaired is left in the joint coverings, accompanied by a more or less extensive loss of subjacent bone involving the articular surfaces, B I P. paste may be smeared over the entire wound surface after excision and the wound closed as far as possible in layers either at once or by delayed suture, after having carefully obliterated dead space with a paraffinised gauze pack. Secondary suture in such a case is a somewhat risky procedure unless all dead space is obliterated. If this cannot be done it is preferable to allow the wound edges to fall in and the wound to heal by granulation.

Use in the treatment of septic arthritis.—Here B.I.P. paste has been largely advocated and not infrequently adopted. The joint is widely opened up and cleaned out. B.I.P. is then distributed over the entire joint surface directly and indirectly by movement. Finally, the joint may be sewn up or left open. In quite a number of the cases where I have seen it used with apparent success I was struck by the fact that nearly all of the cases would almost certainly have settled down had they been left alone and efficiently immobilised. In but few cases was the pulse-rate higher than 100 when treated. B.I.P.P. used in this way inside a joint has a serious drawback: it may be ejected later on as a foreign body and so cause considerable trouble on resumption of movement.

The Use of the Carrel-Dakin Method.

In early cases, after efficient excision of the wound, this method only rarely need be adopted. There is no doubt that simple primary suture or delayed primary suture after using B.I.P.P. yields the better results.

On the other hand, when sepsis develops, in the large majority of cases the Carrel-Dakin method yields the better results. When a wound of any size leading into the joint cavity is more than 36 hours old and appears fairly clean it is well not to adopt any operative procedure, but rather merely to cover the wound with Carrel tubes and, if possible, perform a secondary suture as soon as the condition of the wound allows. The same treatment applies to more recent wounds that are very septic and require excision down to and inclusive of the capsule owing to risk of spread of infection into the interior of the joint. The presence of a retained foreign body may necessitate interference.

Carrel tubes may be inserted into the joint through the original wound, but not shortly after the injury. It is, however, a most useful procedure when it is found that definitely infected fluid is exuding from the joint cavity and it appears probable that the sepsis is localised to one part of the cavity. The tubes should have open ends and be inserted with the utmost care, otherwise adhesions localising the infection may be broken down. Not more than two or three should be inserted at a time even into such a large joint as the knee. They should be changed once every two days—not oftener. The tubes are no longer required when the joint cavity is obliterated save for the tracks occupied by them; these tracks may be obliterated by a firmly applied bandage.

Use after drainage of the joint by free incisions.—Drainage of the joint is the only method of saving the limb in a large percentage of the more septic cases. It is successful if suitably and efficiently carried out. It should, if possible, be combined with the insertion of Carrel tubes into the joint cavity, in a suitable way and in properly chosen situations. These tubes are removed as soon as adhesions have occluded the cavity—i.e., usually from the second to the fourth day; if left *in situ* more than two days they are changed every other day. In some joints, however, the tubes cannot be inserted, and simple arthrotomy yields excellent results—e.g., the elbow.

Excision of the Joint.

This procedure can be used for either early or late cases, and may be either partial or complete. As a rule the object to be aimed at is mobility in the upper limb, stability and bony union in the lower.

Early cases.—Here *complete excision* is best reserved for cases which cannot otherwise be sewn up as a primary measure, which have the end of one or both bones comminuted and which will ultimately yield a useful limb. It is the method of election in the lower limb, especially for the knee-joint, as here fibrous union is liable to yield a flail leg. *Incomplete excision*—i.e., of the end of one bone only or of part of one bone—is of most use in the upper limb and yields excellent results, as it is frequently followed by a fair range of movement. In both forms early or immediate closure is essential to avoid the risk of sepsis and fibrous union in the lower, and to allow of early movement in the upper limb.

Late cases.—Excision as a method of treatment for septic arthritis cannot be advocated as a sound or wise procedure as a general rule. The exposure of large surfaces of newly cut cancellous tissue to severe infection is a dangerous procedure, more particularly when, as so often happens, the infection in the bone has been already localised. In a number of instances I have seen more or less successful results, but these were nearly always in mildly septic cases and such as, I feel sure, would yet have yielded quite satisfactory results without any interference.

In the more severe cases amputation has sooner or later to be resorted to. At one time late excision was widely advocated by the French, but now has largely fallen into disrepute amongst them, and by many is severely condemned. In certain special cases, however, it must be used to save the life or limb of the patient—e.g., in the shoulder, hip, or ankle. In the shoulder and hip it is rendered necessary by the anatomical arrangement of the ends of the bones and of their blood-supply. In the ankle, if the astragalus is fractured to any extent and the joint becomes infected this bone is very liable to a septic osteitis and requires removal; excision of the bone, too, may be necessary merely to allow of efficient drainage of the joint.

When resorting to excision of a joint two methods may be employed according as we desire bony or fibrous union; they are respectively: (*a*) subperiosteal, and (*b*) non-subperiosteal (i.e., the periosteum is removed with the bone). The second method should only be used after the most careful consideration, as there is such a strong tendency for a flail joint to result, particularly if the wound has suppurated for some time. It is well to bear in mind that later on a plastic operation to allow of movement can in many cases be easily and successfully carried out.

Amputation.

This operation is reserved for:—

(*a*) Cases that are too ill to allow of conservative measures being adopted.

(*b*) Cases in which the comminution of bone is so extensive as to preclude the possibility of a successful end-result.

(*c*) Cases accompanied by severe lesions of the main nerves and muscles.

(*d*) Cases in the lower limb accompanied by serious damage to the main vessel and in which there is considerable risk of gangrene.

(*e*) Septic cases, where an extensive osteomyelitis of a large bone—e.g., femur or tibia—is also present.

(*To be continued.*)

SOME ASPECTS OF INFANT FEEDING.

BY J. C. DRUMMOND, D.Sc.

THERE are few problems of nutrition which arouse greater interest at the present time than those which relate to the feeding of infants. Our knowledge of the dietary requirements of the human organism has advanced so rapidly during the last decade that it has led to abandonment of many beliefs and the modification of many fundamental theories. Such a theory was that which taught us that the food requirements of the animal body could be expressed in terms of what had for so long been regarded as the primary food units—the proteins, fats, carbohydrates, and inorganic salts.

It is unnecessary to review here the large amount of research work which has demonstrated the inaccuracy of this theory, for it is now generally accepted that these food units are in themselves insufficient to satisfy the requirements of the animal for growth and maintenance of health, and that there exist a number of indispensable dietary components which are not members of any of these four recognised classes of foodstuffs.

Accessory Factors of the Diet.

It is mainly as a result of the pioneer work of Hopkins[1] in this country that research upon this subject has been stimulated so far that a stage has now been reached when we can almost claim to be able to define the fundamental dietary units. Animals fed upon a diet of pure protein, fat, carbohydrate, and inorganic salts rapidly decline in health and die within a comparatively short time unless they are provided with an adequate amount of certain other dietary factors. These substances received the name "vitamines" from Funk, but chiefly for the reason that this term is very misleading it is now being discarded. These substances are now referred to collectively as the accessory factors of the diet. So far the existence of three individual substances of this type has been detected. At least two of these are of primary importance for growth, whilst all three are undoubtedly necessary for the preservation of health.

The provisional and non-committal names which have been allotted to these factors are as follows: (1) Fat-soluble A"; (2) "Water-soluble B," or anti-beri-beri (anti-neuritic) factor; and (3) "Water-soluble C," or antiscorbutic factor. As yet practically nothing is known of the chemical nature of any one of these substances.

The object of the present paper is to draw attention to the influence of these factors on infant nutrition. Unfortunately, those interested in the science of infant feeding are only just beginning to appreciate the vital importance of these substances for growth, and one still encounters many misleading and inaccurate statements about them.

"Fat-soluble A" is synthesised by the plant and is found present in most green leaves and in the embryos of certain cereals. Such foodstuffs constitute the primary sources of the factor for the animal organism, which, apparently, does not possess the power to synthesise it. In the embryos of seeds this substance probably occurs in loose combination with protein, but when liberated, as it is during digestion, it shows similar solubilities to the fats and lipoids, and accompanies these substances during absorption. The growing animal demands a liberal supply of this factor, but we are ignorant as to the exact rôle it plays in the body. The adult can maintain good health upon a much smaller intake. Probably in both cases any excess of intake over and above the actual requirements for growth or tissue repair is stored in company with depôt fat. Young animals deprived of this factor in their diet usually show no ill effect for a little time, during which it is probable that they are drawing upon their reserve supplies to make good the deficiency. Sooner or later, however, growth ceases, and they exhibit a greatly impaired resistance to disease, which usually results in an early death from acute infections, particularly of the lungs. Prompt correction of the inadequacy in the diet by the inclusion of some foodstuff containing an ample amount of the missing factor results in a more or less rapid recovery of health, and ultimately the resumption of a normal rate of growth.

The "water-soluble B" is probably identical with the dietary factor that has been termed the anti-beri-beri vitamine.[2] The diseases known as beri-beri and infantile beri-beri represent, however, the final pathological condition induced by a deficiency of this factor in the diet. Long before such syndromes appear the deficiency manifests itself in a retardation or inhibition of growth. Young animals show absolutely no growth when entirely deprived of this dietary unit, and it is only after this inhibition has been maintained for some time that the typical symptoms of nerve incoördination appear. The animal cannot synthesise "water-soluble B," and is therefore entirely dependent upon the plant kingdom for its supplies. Cereal embryos and yeast are the richest known sources amongst the natural foodstuffs.

The antiscorbutic factor, or, as we may now term it, "water-soluble C," is probably indispensable to all growing animals, although many species exhibit a very slight susceptibility to scurvy, and therefore require very small amounts of the protecting substance. As in the case of the factors "A" and "B," the animal is primarily dependent upon the plant kingdom for the substance "C," which chiefly occurs in fresh vegetables and fruits.

The following tables indicate the chief properties of the three substances, and give a short guide as to their distribution in natural foodstuffs:—

TABLE I.

A — "Fat-soluble A." B — "Water-soluble B," or anti-beri-beri factor. C = "Water-soluble C," or anti-scorbutic factor.

—	A.	B.	C.
Stability to temperature.	Stable at 100° C., probably stable at 140° C.	Comparatively stable at 100° C. Slowly destroyed at 120° C. and above.	Gradually destroyed above 50° C. Rapidly destroyed above 80° C.
Stability to alkalies.	Stable in cold, possibly stable when hot.	Slowly destroyed in cold. Rapidly destroyed when hot.	Rapidly destroyed even when cold.
Stability to acids.	Probably stable.	Comparatively stable.	Comparatively stable below 50° C.

TABLE II.—*Distribution of Accessory Factors in Natural Foodstuffs.*

A = "Fat-soluble A." B = "Water-soluble B," or anti-beri-beri factor. C = "Water-soluble C," or antiscorbutic factor.

A rough attempt has been made to give some idea of the relative values of foodstuffs containing the factors by employing more than one positive sign. A negative sign indicates the absence of a factor, whilst an interrogation mark shows either a doubtful result or that no investigation has been made.

During the last few years I have carried out a large amount of experimental research on the influence of accessory substances upon the nutrition of young growing animals. For these experiments I have employed the rat, an animal which has many times been proved to be of the greatest value for such a purpose. The results I have obtained may have, I believe, in many cases an important bearing upon child nutrition, and for that reason I am putting forward certain suggestions, based upon practical

experience, which I trust will engage the attention of those who possess a wide knowledge of the practical side of infant feeding.

These experiments upon animals have demonstrated the absolute indispensability of an adequate supply of the accessory factors during the period of growth. Since there is a certain amount of evidence in favour of the view that these substances are quantitatively utilised during tissue formation, it follows that the demand for them will be greatest during the period of most rapid growth—that is, during very early life.[3]

What I wish to emphasise with all possible force is that the food-supply need not be entirely deficient in a factor such as these in order to bring about nutritive failure. A very slight inadequacy operating over a considerable period may be the cause of an apparently insignificant, but in reality very serious, disturbance of the health of the growing child, the effects of which may be marked long after the deficiency has been corrected.

Breast Feeding.

Experimental research has recently shown that the nursing mother is dependent upon her food-supply in order to provide her young with the accessory factors. Physiological evolution has elaborated a wonderful mechanism whereby the composition of the milk is, as far as possible, protected against the effects of dietary restrictions. But this protective process does not appear to extend to the accessory factors. Sacrifice of the mother's own tissues will frequently tide over a period of dietary deficiency as regards protein or energy intake, but only in the case of the "fat-soluble A" can she indirectly make good an inadequacy of accessory factors, and then only to the extent of calling up any reserves of that factor which she may possess. It should, therefore, be appreciated how vitally important is the necessity for an adequate supply of the accessory factors in the dietaries of expectant or nursing mothers. In fact, I go as far as to say that public authorities should emphasise this point with as much vigour as they do the importance of breast-feeding.

If the mother does not receive an adequate supply of these substances two results follow. First, what she does receive probably goes into her milk, for physiological evolution undoubtedly demands development of the child even at the expense of the mother, therefore she herself suffers the effects of a very serious deficiency; and, secondly, the young, in spite of the maternal sacrifice, receive an insufficient amount of the factor for normal nutrition.[4]

This point may be illustrated by the following experimental results obtained with rats.

A young adult female rat was placed upon a diet seriously deficient in "fat-soluble A" as soon as it was observed that she was pregnant. Eight young of normal weight were subsequently born, of which four were destroyed to reduce the task of rearing. For over a fortnight the surviving young grew at a normal rate, during which time it is surmised that the mother was correcting the dietary inadequacy by drawing upon her own reserves of the factor, but they then began to show signs of failing health. The rate of growth declined and both they and their mother showed great susceptibility to infection, particularly a form of external eye disease which will be described subsequently. Two of the young died 31 days after birth from pyogenic infections, and both the mother and the surviving young were then given a normal dietary. One of the young failed to recover, having lost the sight of both eyes and contracted an infection of the lungs, but the mother and the remaining youngster survived and slowly regained their health. After 40 days from birth the young rat appeared normal, and resumed a normal rate of growth upon the adequate ration.

Such a case is typical of a very large number, and exhibits what may be the consequences of a serious deficiency of one factor in the diet. It is improbable that deficiencies of so serious a nature would occur in this country, where even the poorest classes are able to obtain a mixed diet. On the other hand, there is considerable danger that the cost of the chief foodstuffs which serve as sources of the "fat-soluble A"—milk, butter, and eggs—may result in a large number of mothers attempting to nurse their young whilst themselves receiving a dietary more or less inadequate in that factor.

I have carefully followed the results of feeding considerable numbers of rats upon such dietaries, and believe that they may serve to explain certain types of malnutrition so common in the lower classes. As described above, the young rats when born are usually of normal weight unless the mother has suffered from the restriction for some time previous to delivery, when, of course, her reserves may be already near exhaustion. They may also show throughout the period of dependence upon their mother a normal, or only slightly subnormal, rate of growth. But what is most important is that they never exhibit a normal standard of resistance to disease. Amongst rats this very frequently takes the form of a peculiar susceptibility to a characteristic form of external eye disease, which has been classified as a xerophthalmia.

The condition may be only slight if the dietary inadequacy of "fat-soluble A" is also slight; but, on the other hand, it may be so severe as to involve the cornea and result in permanent blindness. I make the suggestion here that much of the low resistance to disease shown by the young of the poorer classes in this country is indirectly due not to any deficiency of protein or calories, but to their having received during a most critical period of their development an inadeqate supply of one or more of the indispensable accessory factors.

Fortunately our varied dietary in this country precludes any great danger from a deficiency of the "water-soluble B," and we need therefore not fear the incidence of conditions as severe as infantile beri-beri. Nevertheless, we should therefore take due precautions to ensure an adequate supply of this factor to the nursing mother.

Equally important is the necessity of providing the suckling child indirectly through the diet of the mother with a sufficiency of the antiscorbutic factor. I have not been able to work this point out experimentally, as the rat shows an extraordinarily low susceptibility to scurvy. This, however, is not so with the human infant, and we must remember that serious damage to health, perhaps with life-long effects, may result from a failure to supply the child with an adequate amount of this substance, although it may be receiving sufficient to prevent the incidence of the typical syndrome of scurvy.

Feeding with Cow's Milk or Modified Milk.

Since the rate of growth of the calf is greater than that of the child we have a certain amount of right to assume that cow's milk is an adequate source of the accessory factors for the growing human infant. This assumption appears to be supported by the fact that children can in certain cases thrive from a very early age on unmodified cow's milk. Perhaps, in such cases, it is wise to guard against a possible deficiency of the factor "C" by occasional administrations of orange juice,[5] for the cow probably represents a species with a low susceptibility to scurvy, and therefore its milk contains little of the antiscorbutic substance.

The modification of cow's milk for infant feeding is a most important problem. In the past pediatricians have had as their aim the preparation of a fluid resembling human milk in its gross composition, and they have therefore made their calculations solely in terms of protein, fat, carbohydrate, and inorganic salts. Such a basis must now be discarded in favour of one which takes full account of the important accessory factors which we have described. If the modification of cow's milk is carried out only with products derived from milk there is little danger that a foodstuff deficient in the growth factors will be obtained. It should therefore be impressed upon all who have to carry out the modification of milk that true success will only be achieved by the employment of such units as cream and whey.

Too little attention is frequently paid to the source of fat used in modifying milk. For instance, one widely adopted substitute for cream is what has been termed "Marylebone cream," a preparation which is in reality an emulsion of linseed oil. This is added to a separated milk product and must therefore result in the production of a foodstuff very seriously deficient in "fat-soluble A," for it has been shown that vegetable oils do not contain this factor.[6] Olive oil, another oil inadequate in this respect, is also employed to no inconsiderable extent for a similar purpose. I have no knowledge what results have been obtained in the feeding of infants with such preparations, but from my experience with animals fed on food mixtures showing the same deficiency I believe it will be found that such children will show a seriously diminished resistance to disease in spite of their having, perhaps, shown a normal development.

Dried and Condensed Milk.

Dried milk is employed very extensively at the present time in infant feeding, and from the very fact that such excellent results are being obtained it appears that the accessory factors which influence growth are being supplied in a sufficient amount. The majority of dried milk is prepared by one or other of two processes, which we may term the "drum" and the "spray" processes respectively. In the former the exposure to a high temperature is probably insufficient to cause any appreciable destruction of factors "A" and "B," but it appears that the antiscorbutic principle may suffer. In the spraying processes, however, the dried milk powder remains in the chamber heated by a current of air at 115° C., presumably until sufficient material has been collected. If this period extends over an hour or two a certain amount of destruction of the water-soluble growth factor may be caused. The majority of condensed milks are prepared by processes which should effect a very inappreciable destruction of the factor "B," and unsweetened condensed whole milk should, when carefully diluted, be an adequate source of the two growth factors "A" and "B." There is, however, very considerable danger in the employment of the other forms of condensed milk. The use of these products is discouraged on the ground that they are, when diluted according to the directions given on the package, seriously deficient in fat for infant feeding. We are here faced by a very important problem. Characteristic symptoms of malnutrition have often been described as following the use of fat-deficient infant foods, and it is most interesting that these symptoms are closely similar to those which are now associated with a deficiency of the indispensable "fat-soluble A." We may therefore ask whether a deficiency of fat is in itself a serious matter for the infant, or whether nutritive failure does not rather result from a restricted supply of the accompanying accessory factor. Personally, I believe the latter view is correct, and that mere corrections of the fat deficiency by the addition of a fat which does not contain the accesssory would effect little, if any, improvement in the health of the child, whereas the employment of an adequate fat, such as butter or cod-liver oil, would at once restore the subject to health. I put forward this suggestion purely as a result of experimental work with rats, and hope that those who make an extensive study of the subject of the artificial feeding of infants will give it some attention.

Proprietary Infants' Foods.

These substitutes for mothers' milk must from their composition in many cases be seriously deficient in both accessory factors "A" and "B," but particularly in the former. Many of them are fat-deficient, and therefore equally deficient in the indispensable accompaniment to milk fat. Here again we may have a partial explanation of the characteristic liability to infection which is so frequently shown by the fat but pasty baby reared upon this type of food. Such dietaries should be adequately supplemented with rich sources of this factor in the form of cream or cod-liver oil, otherwise malnutrition will inevitably follow.

I have not touched on the important subject of infant scurvy because my experimental work with rats has given me no opportunity of studying that deficiency disease. This aspect of the problem has, however, been very fully treated by other workers in a previous paper which appeared in THE LANCET.[5]

It now remains for the practical worker on infant nutrition to apply the results of these experimental studies as soon as he is convinced of their accuracy.

ROYAL SANITARY INSTITUTE.—A visit has been arranged to Messrs. Pilkington's Tile and Pottery Co.'s Factory, Clifton Junction, at 2 P.M., on Friday, Oct. 18th, and at 6.30 P.M. a discussion will take place at the College of Technology, Manchester, on "Welfare Work in Factories and Workshops," to be opened by Professor J. Radcliffe, M.Sc.Tech., and Miss Ethel Brown (welfare secretary to Messrs. John Bright and Brothers, of Rochdale). The chair will be taken by Dr. Philip Boobbyer. Tickets from the secretary of the Institute, 90, Buckingham Palace-road, London, S.W. 1.

PROPHYLACTIC VACCINATIONS

AGAINST CATARRHAL AFFECTIONS OF THE RESPIRATORY TRACT.

BY JOHN W. H. EYRE, M.D. DURH.,

DIRECTOR OF THE BACTERIOLOGICAL DEPARTMENT, GUY'S HOSPITAL;

AND

C. E. LOWE, M.D.,

CAPTAIN, N.Z.E.F.; PATHOLOGIST TO THE N.Z. GENERAL HOSPITAL, WALTON-ON-THAMES.

AMONGST those who are in the habit of employing vaccines therapeutically in civilian practice the impression has steadily gained ground that sufferers from catarrhal conditions of the respiratory tract are benefited by inoculations prophylactically administered. So far as we know, however, there have never been recorded any extended observations bearing upon the immunity obtained by the ordinary soldier from the prophylactic use of "mixed" vaccine against respiratory catarrh, although Wright[1] and Lister[2] employed pneumococcus vaccines for the prevention of pneumonia in the South African miner and Cecil and Austin[3] used similar vaccines for the protection of the American soldier.

As we have recently had the opportunity of carrying out such a series of inoculations, on a scale which permitted the observation of a nominal roll of 1000, we believe it might be of interest to record our results.

Outbreak of Measles and Rubella Complicated by "Purulent Bronchitis."

During January, 1918, 327 cases of measles and rubella, all of a mild type, were admitted to hospital from a certain camp occupied by the *n*-th Reinforcement of the New Zealand Expeditionary Force, which had arrived in England on the 7th and 9th of the month. During February a further 124 cases were admitted, and of these 24 died.

In consequence of this heavy mortality one of the present writers was detailed, together with Lieutenant-Colonel H. French, R.A.M.C., consulting physician to the Aldershot Command, to investigate the outbreak. In all some 33 cases were inspected, and it at once became apparent that the exanthem was usually complicated by "purulent bronchitis" identical in its clinical features with the outbreak of purulent bronchitis investigated by the same observers in the Aldershot Command during the early part of 1917—that is to say, apart from the rash of the primary measles or rubella, often very indistinct and atypical, the physical signs were insignificant, usually only a few scattered rhonchi, but in all the sputum was abundant, consisting of pure pus, in most instances greenish-yellow, but in two cases reddened by altered blood. In the recent and severe cases cyanosis was pronounced, although the patients were lying flat and not in great distress.

Fourteen cases were selected for detailed bacteriological examination. Of these, three died, and observations were made on the post-mortem material thus rendered available. An autopsy was also made upon an Imperial officer from the same area, who—unconnected in any way with the N.Z.E.F.—had died from purulent bronchitis uncomplicated by any exanthem.

Speaking generally, the bacteriological findings were very similar. *B. influenzæ* was present on one or more occasions in 12 of the 14 sputa examined, usually associated with *Streptococcus longus* and various types of *Micrococcus catarrhalis*. In the fatal cases the heart blood and spleen showed the presence of *Streptococcus pyogenes longus* with marked hæmolytic properties. Thus the analogy with the cases of purulent bronchitis observed the preceding year[4] was complete; there was evidence of a primary infection of the respiratory tract by *Bacillus influenzæ*, which so lowered the resistance of the individual that secondary infection by the *Streptococcus pyogenes longus* (and not the pneumococcus, as in the Aldershot epidemic) ensued, and in many instances resulted in an acute and rapidly fatal streptococcic septicæmia.

[4] Purulent Bronchitis. By Abrahams, Hallows, Eyre, and French, THE LANCET, Sept. 8th, 1917, p. 377.

The morbid histology of the pulmonary tissues was similar to that detailed in the "Aldershot" report and consisted chiefly of a purulent bronchitis and peribronchitis associated with areas of œdema, areas of collapse, and patches of lobular broncho-pneumonia, whilst at the bases of the lungs the process tended to involve larger areas, and, in rare instances, to progress to complete consolidation.

The incidence of rubella and morbilli must be regarded, in many instances, as a predisposing cause producing the initial lowering of resistance which facilitated the entry of the *Bacillus influenzæ*; in other cases the eruptive fever appeared to be merely a coincidence.

Details of Cases.

Fatal Cases.

CASE 1.—Admitted Feb. 7th, 1918. Rubella (rash appeared Feb. 5th) and bronchitis. Seen during life—cyanosed—*in extremis*. Typical purulent nummular sputum. Died 3 P.M., Feb. 24th.

Post-mortem same day 5 P.M. (therefore post-mortem decomposition changes negligible). (*a*) *Lung—Naked-eye*: Practically sound externally; no consolidation; cut surface exuded thick yellow pus, in some parts frothy. Œdema and collapse. *Microscopically* the condition was one of purulent bronchitis, bronchiolitis and peri-bronchiolitis, with areas of collapse and areas of œdema. Small patches of broncho-pneumonia were present. *Cultures* gave a growth in which, although *B. influenzæ* were present, *Streptococcus pyogenes longus* and *Micrococcus catarrhalis* were the predominant bacteria. (Cultures from the upper lobe showed more *B. influenzæ* than those from the lower lobes.) (*b*) *Heart blood culture*: *Streptococcus pyogenes longus*. (*c*) *Kidney*: Early cloudy swelling, albumin in tubules, hæmorrhage into some glomeruli, few Gram-positive diplococci observed. (*d*) *Liver*: No gross changes; in some parts the liver cells showed some vacuolation.

CASE 2.—Admitted Feb. 8th, 1918. Rubella (rash appeared on Feb. 7th). Bronchitis developed and a second rash (measles) appeared on Feb. 20th. Seen during life: Feb. 24th: T. 101°, P. 130, R. 40; marked cyanosis; typical nummular purulent sputum; very few signs in chest; no consolidation. *Sputum*: Pus cells, Gram-negative intracellular minute bacilli, few Gram-negative micrococci, Gram-positive cocci in pairs and short chains. *Cultures*: *B. influenzæ*, *Micrococcus catarrhalis*, *Streptococcus pyogenes longus*, *Diplococcus pneumoniæ*. Died during the night of Feb. 24th–25th.

Post-mortem, Feb. 25th.—(*a*) *Lung—Naked-eye*: Consolidation at base, especially right (pieces sank in water). Upper lobes: Patches of broncho-pneumonia. Middle lobe right: No marked changes beyond shotty feel of cut bronchioles; cut surface exudes purulent and frothy mucus. Bronchiolitis and purulent bronchitis. *Microscopically*: The bases showed large areas of pneumonia, progressing in places towards gangrene. Upper lobe: Numerous hæmorrhages and small patches of broncho-pneumonia. Middle right lobe: Purulent bronchitis and peribronchial infiltration, with small cells. (*b*) *Spleen cultures*: *Streptococcus pyogenes longus*. (*c*) *Heart blood cultures*: *Streptococcus pyogenes longus* associated with a few *B. coli*. (*d*) *Pericardial fluid cultures*: *Streptococcus pyogenes longus* (conglomerate masses).

A third post-mortem was carried out upon an Imperial officer. The history supplied was:—

Operation on nose Jan. 24th, 1918, Officers' Hospital. Discharged Jan. 28th. Sick in quarters Feb. 2nd, after a long motor ride, ? influenza. Readmitted Officers' Hospital Feb. 11th with bronchitis. Sputum frothy; mucopurulent; profuse in amount; bacteria few in number; streptococcus predominant. Cyanosis; oxygen administered. Died on Feb. 23rd.

Post-mortem, Feb. 25th.—Appearances of the lung were practically identical with those noted in Case 2. Owing to the interval that had elapsed between death and the autopsy no material was taken for cultures or for sections, but exudation from bronchi, when examined microscopically, showed pus cells and intracellular Gram-negative minute bacilli, in addition to numerous other bacilli and cocci, evidently representing numerous varieties.

Severe Case.

CASE 3.—Feb. 24th, 1918: Rubella and bronchitis. T. 101°, P. 126, R. 32. Very marked cyanosis. Typical sputum. Fine crepitant râles all over chest. No consolidation. *Blood culture*: Scanty growth of *Streptococcus pyogenes longus*. *Sputum*: *Microscopically*—pus, Gram negative intracellular minute bacilli, many simulating diplococci, also Gram-positive cocci in chains and some Gram-negative cocci. *Cultures*: *B. influenzæ*, diphtheroids, short chains of Gram-positive cocci, very few *Micrococcus catarrhalis*. This patient died two days later.

Subacute and Convalescent Cases in Ward 6.

Ward 6 contained 11 patients, all of whom were stated to have had purulent sputum on admission.

CASE 4.—Rubella and bronchitis. Typical sputum. Dullness in right mid-axillary line. *Lung puncture*: Only a few drops of blood withdrawn. Cultures remained sterile. *Sputum* on two occasions (Feb. 24th and March 5th) gave similar bacteriological findings, although the second specimen, naked eye, was less typical and distinctly frothy. *Cultures* on each occasion gave a growth of *B. influenzæ*, *Streptococcus longus*, and diphtheroid bacilli.

CASE 5.—Rubella and bronchitis. Typical sputum. Convalescent; scroopy rhonchi all over chest, but both lungs resonant. (Blood cultures on Feb. 16th stated to have given (?) pneumococcus). *Sputum cultures*: *B. influenzæ*, *Streptococcus longus*, few *Micrococcus catarrhalis*.

CASE 6.—Rubella and bronchitis. *Sputum*: March 5th, 1918. *Cultures*: Very mixed growth; some *B. influenzæ* present, but large numbers of *Staphylococcus aureus*, *Streptococcus pyogenes longus*, *Streptococcus brevis*, and *Micrococcus catarrhalis*.

CASE 7.—Rubella and bronchitis. Convalescent, but still some cyanosis. *Sputum*: Few purulent pellets in abundant frothy mucus. *Microscopically*: Very few Gram-negative intracellular bacilli; numerous Gram-positive cocci. No cultivations made.

CASE 8.—Rubella and bronchitis. Marked cyanosis. Prune-juice-coloured purulent sputum. Sticky non consonating râles all over chest. *Sputum*: Feb. 24th, 1918. Pus cells, blood cells, Gram-negative intracellular bacilli, Gram-positive diplococci. *Cultures*: *Micrococcus catarrhalis*, *Streptococcus longus*, *B. influenzæ*.

Subacute and Convalescent Cases in Ward 7.

CASE 9.—Rubella and bronchitis. Cyanosis; typical sputum. *Sputum*: Pus cells and intracellular Gram-negative minute bacilli and diplococcoid forms. *Cultures*: No growth occurred; presumably the tubes were never inoculated.

CASE 10.—*Sputum cultures*: No *B. influenzæ* could be detected. Growth mainly *Streptococcus longus* and *Micrococcus catarrhalis*.

CASE 11.—*Sputum cultures*: Showed only a few *B. influenzæ*, numerous streptococci, both of the longus and brevis types, and *Micrococcus catarrhalis*.

CASE 12.—*Sputum cultures*: No *B. influenzæ* could be detected. The growth was a mixed one of *Streptococcus longus* and *Micrococcus catarrhalis*.

CASE 13.—Rubella and bronchitis. T. 102°. Reddish brown (but not typically "rusty") purulent sputum. *Blood cultures*: Scanty growth of *Staphylococcus aureus*. *Sputum cultures*: *B. influenzæ* and *Staphylococcus aureus*. A second specimen of sputum (March 5th) gave almost identical cultures, consisting of *B. influenzæ*, associated with *Staphylococcus aureus*.

Subacute and Convalescent Case in Ward 8.

CASE 14.—Rubella and bronchitis. Cyanosis and typical purulent nummular sputum with intracellular Gram-negative bacilli, resembling *B. influenzæ*.

The few blood counts that were made showed a slight but distinct polymorphonuclear leucocytosis, not only relative, but also absolute. The red cells averaged 4,500,000, and the leucocytes ranged from 10,000 to 12,000. The differential leucocyte count in 8 cases was as follows:—

Case No.	1	3	4	5	7	8	12	14
Polymorphs	77	78·5	81·5	74	64	81	81	77
Lymphocytes	19	19	15·5	23·5	33	15	17	20
Large mononuclears	3	2	2	2	2	2·5	1·5	3
Eosinophiles	1	0·5	1	0·5	1	1·5	0·5	0

Prophylactic Vaccination.

On account of the severity of the infection affecting the Colonial troops in question, and bearing in mind the susceptibility of the average New Zealander to infections of the respiratory tract, and also because of the definite bacteriological findings as stated above, it was thought well to advise the N.Z. medical headquarters of the desirability of attempting, in addition to the improved sanitary measures adopted at the camps, to attempt to immunise reinforcements by prophylactic vaccination against catarrhal infection. This measure was at once authorised and arrangements were accordingly made for the vaccination of the entire personnel of the two most recent reinforcements in England. So promptly did the N.Z. medical headquarters act that within 14 days not only had a large amount of "mixed" vaccine been prepared (from cultivations derived from the cases already detailed), but the initial dose had been administered to several thousand men.

The vaccine was prepared in two different strengths, the weaker initial dose being followed ten days later by the second stronger dose—in each instance the volume of vaccine administered amounted to 0·5 c.cm.

Our first concern was to determine whether initial reactions would prove at all severe and thereby interfere with the necessary training of the troops inoculated. For this purpose reaction record sheets were prepared and sent to each area concerned, together with the following memorandum describing the vaccines and indicating the reactions likely to be observed:—

N.Z.E.F.

Mixed Catarrhal Vaccines for Prophylactic Inoculation against Purulent Bronchitis and Respiratory Catarrhs.

Description of vaccine.—A multiple vaccine has been prepared from organisms contained in the secretions of purulent bronchitis and in the sputa of other catarrhal cases among the troops of England. It contains:—

Organism.	1st dose.	2nd dose.	Organism.	1st dose.	2nd dose.
Pneumococcus	50 ...	100 million*	*M. catarrhalis*	25 ...	75 million.*
Streptococcus	10 ...	50 ,,	*B. pneumoniæ*	50 ...	100 ,,
B. influenzæ	10 ...	30 ,,	*B. septus*	50 ...	100 ,,
Staph. aureus	200 ...	500 ,,			

* Organisms per 0·5 c.cm.

This vaccine has been designed to produce an artificial immunity, not only against the first three virulent organisms, which are frequently found present in fatal purulent bronchitis, but also to immunise against the other organisms most frequently found in

catarrhal sputa and nasal discharges. Its multivalency will not depreciate its value against the more serious cases or prohibit its usefulness in the less serious infections.

Dosage.—The vaccine is prepared for use in two strengths, as described above, each being distinctly labelled for first and second doses. The amount of vaccine to be given on each occasion is 0·5 c.cm; the second inoculation, with the stronger vaccine, to be given after an interval of ten days. In cases which give a severe reaction after the initial dose the second dose should be given, but after a longer interval—say 14 days. Where the prodromal symptoms of measles, &c., are suspected the prophylactic vaccine should not be used, but that arranged for *treatment*, which contains considerably smaller doses and is being prepared.

Reactions to be Expected.

1. *There may be no reaction*, but in such cases the immunity conferred may be as efficient as in those who react. 2. *There may be slight reaction.* This is the most likely sequela, and will probably occur during the 24 hours following inoculation and, apart from a possible tenderness at site of injection, may produce a mild general malaise, tiredness, stiffness, and slight headache. In cases with existing catarrhal discharges these may be temporarily aggravated. 3. *There may be severe reaction.* This is not expected except in a small percentage of cases. Such will develop during the following 24 hours an aggravated condition of the above symptoms, and also probably a rise of temperature and pulse-rate. In these cases at least 14 days should be allowed to elapse before the second dose is given. Severe reactions may possibly occur if the occasion of inoculation happens to coincide with the onset of measles, &c. *Inoculated men should be excused duty for 24 hours.*

Immunity.—The immunity conferred will probably not last longer than 12 months, and it should not be forgotten that there is always a certain percentage of persons in whom it appears impossible to produce any immunity.

Records.—The date of both catarrhal vaccine inoculations should be entered in each man's pay-book, and the letters "M.C.V." (which mean mixed catarrhal vaccine) should be adopted to indicate when the man was inoculated and to prevent the occasion of his catarrhal inoculation being confused later with that of his T.A.B. or A.T.S. inoculations. If men refuse inoculation the fact should be written or stamped in their pay-book, "Refused M.C.V. inoculation," and the date. It will be of great value to have all available data of the immediate result of these inoculations as regards reactions, and for this purpose "reaction record sheets" are enclosed, upon which the reaction results can be entered, and when the bulk of men have been inoculated for the second time these sheets must be forwarded as soon as possible to Medical Headquarters, London, to be sent on to Captain Lowe, N.Z.M.C., pathologist.

Through the details of these returns, so thoroughly filled in by the R.M.O.'s, the following data have been obtained:—

(A) 2081 men inoculated with the initial dose. (B) 1627 men inoculated ten days later with the second dose.

	(A)	(B)
No reaction	2033 = 97·7 per cent.	1607 = 98·8 per cent.
Slight reaction	42 = 2·0 ,,	13 = 0·7 ,,
Severe reaction ...	6 = 0·3 ,,	7 = 0·4 ,,

As *slight reaction* the M.O.'s in charge note: Headache in 24 cases; temperature from 99°–101° in 14; sore throat in 5; neck stiffness, nausea, and fainting in 5.

As *severe reaction* the above symptoms, more marked and accompanied by temperatures between 101° and 104°, are the points noted.

All the men were excused duty for 24 hours on the occasion of both inoculations, and the incapacity occasioned by the severest reactions did not last for more than 72 hours. However, in spite of there being so small evidence of immediate reactions, there was no doubt an increased susceptibility to the prevalent catarrhs of the area, as will be pointed out below, where the records of respiratory complaints in 1000 inoculated men are detailed.

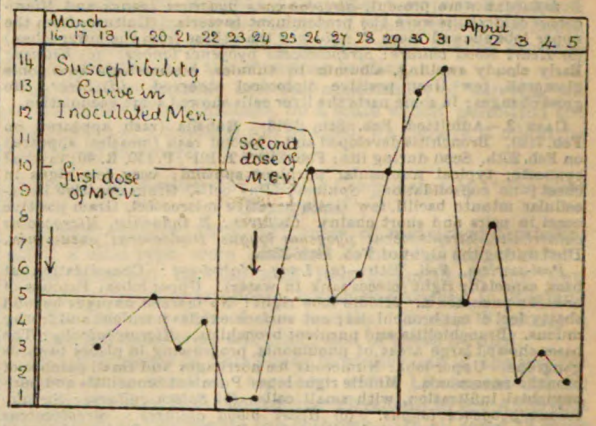
Statistical Record of Results of Vaccination.

Having thus obtained data that showed that the extensive use of catarrhal vaccine would not incapacitate troops in training to any appreciable extent, the next step was to endeavour to obtain some kind of statistical records as to whether these inoculated men had gained any appreciable immunity to respiratory catarrhal complaints, which are the special bugbear of Colonial troops in England. For this purpose a nominal roll was made of the first 1000 men inoculated, and week by week all entries referring to any respiratory complaints reported have been collected.

Further, it was intended to compare these with exactly similar reports received from another selected 1000 men of a reinforcement which arrived in England about six weeks earlier and none of whom had been inoculated with this, or as far as we know, any other catarrhal vaccine. This, however, proved impracticable, and therefore an average of all respiratory complaints occurring per 1000 among the uninoculated N.Z. Troops in the United Kingdom has been arranged as a comparison. The figures thus obtained have been collected independently by the Officer in Charge of Medical Statistics N.Z.E.F., and cover a period from March 15th, 1918, to August 18th, 1918, the prophylactic inoculations being given on or about the 16th and 26th of March respectively.

The experimental work upon which prophylactic, and still more therapeutic, vaccination was originally based showed clearly that, quite apart from the immediate local and general reactions, there supervened a period of lowered resistance or increased susceptibility towards infection by micro-organisms of the same species as those constituting the antigen, and that this so-called "negative phase" varied in extent from a few hours to two or three weeks, in accordance with the size of the dose of antigen, the general physical condition of the inoculated subject, and other factors. We were, of course, fully alive to this aspect of our experiment, and anticipated that during the seven days following the first inoculation and the ten days following the second, there would be an increase in the number of catarrhal affections reported from the troops comprising our nominal roll, and in order that none might be missed arrangements were made for all these cases to be admitted to hospital for observations.

The accuracy of our surmise was proved by subsequent events, as will be seen from the accompanying curve,



showing the relevant admissions from day to day for a period of three weeks from the date of the initial inoculation. Thus 15 admissions were reported between the administration of the first and second doses of M.C.V., and during the ten days following the injection of the second—much larger—dose of vaccine no less than 82 cases were admitted. Of course, most of these were quite trivial, and in the ordinary course of events, and amongst uninoculated men, would never have been admitted, but, nevertheless, even when heavily discounted, these figures emphasise the reality of the "negative phase," and prompt the suggestion that the initial dose might, with advantage, have been somewhat larger, or preferably that the interval between the two inoculations should have been a few days longer.

The subsequent behaviour of our nominal roll towards infections of the respiratory tract is shown in the accompanying table, where the relevant admissions are paralleled with the corresponding admissions per "average 1000" uninoculated N.Z.E.F. in the United Kingdom, to the marked advantage of the former.

Records of Admissions to Hospital with Respiratory Complaints

(A) Of Nominal Roll of 1000 Inoculated N.Z. Men. (B) Of per average 1000 Uninoculated N.Z. Men in United Kingdom.

Week ending—	(A)	(B)	Week ending—	(A)	(B)
April 12th	2	4·3	June 28th... ...	1	14·2
,, 19th	1	3·2	July 7th... ...	0	5·0
,, 26th	0	4·0	,, 14th... ...	0	3·1

,, 10th	1	3·2	,, 28th... ...	0	1·0
,, 17th	2	4·3	August 4th... ...	0	2·0
,, 24th	2	3·3	,, 11th... ...	0	1·4
,, 31st	0	3·3	,, 18th... ...	0	1·1
June 7th	0	4·0			
,, 14th	1	3·2			
,, 21st	0	7·0	Total	12	73·1

The few serological tests we were able to carry out, and to which reference is made below, indicated that an immuno-

logical response had been made by some of the inoculated individuals to the prophylactic vaccinations, but in June Nature stepped in and provided clinical proof of the protection conferred, for in this month a widespread pandemic of "influenza" commenced. The bacteriology of this epidemic has been variously reported upon by different observers, of varying experience, from different areas, with the result that *B. influenzæ*, pneumococci, *Micrococcus catarrhalis*, and other allied organisms have all been implicated. Our own opinion, based upon the examination of material derived from cases occurring in widely separated parts of the United Kingdom, is that *B. influenzæ* was the prime factor in this epidemic, but was associated, particularly in the severe cases, with various other catarrhal organisms (all represented in the strains from which our M.C. vaccine was compounded), and an examination of the figures from our nominal roll shows that the incidence of the "influenza" epidemic was appreciably less amongst the inoculated men than that affecting the "average 1000" of the uninoculated New Zealanders (2 per 1000, as against 28·4 per average 1000), a result which amply justifies the prophylactic use of M.C.V.

Serological Tests.

When the initial inoculations were being undertaken, it was decided to collect samples of blood from a small group of men both before and several weeks after inoculation, with the object of demonstrating by laboratory methods the presence or absence of immune bodies or their subsequent increase in the blood sera.

For this purpose the S.M.O.'s at three different camps in which inoculations were being arranged selected men who on account of their duties were likely to be still available four or five weeks later. In this way 30 samples of blood were obtained and five weeks later a second sample was obtained from 20 of these—the other 10 were not available, having been despatched to other depôts or to France.

Agglutination reactions were carried out microscopically with emulsions prepared from 24 hours' subcultures of each of the seven component organisms of the catarrhal vaccine employed, the dilution of sera used in each case being 1 in 20 and 1 in 200. Throughout the whole series of experiments the greatest care was exercised to maintain uniformity of technique, and all doubtful reactions were repeated and discarded if still doubtful. Controls of sterile saline and rabbits' serum were used with each batch of reactions.

The data given below also included the agglutination reactions obtained as a comparison by using the sera (individually) of 10 English soldiers who had not received any catarrhal vaccine and had not suffered more than ordinarily from catarrhal complaints. This group was included to ascertain whether the average English born and bred soldier has a better natural immunity to the prevalent organisms of catarrh than the average Colonial soldier. The results obtained are as follows:—

Serum of 20 N.Z. Soldiers showing Agglutinins Present. (A) Before Inoculation. (B) After Inoculation.
(C) Serum of 10 English Soldiers showing Agglutinins Present.

Organism.	(A)	(B)	(C)	Organism.	(A)	(B)	(C)
	%	%	%		%	%	%
Pneumococcus	20	85	30	*Micrococcus catarrhalis* ...	40	85	40
Streptococcus longus ...	10	75	30				
B. influenzæ	20	95	50	*B. pneumoniæ* ...	0	40	60
Staph. aureus	90	100	90	*B. septus*...	15	80	40

These percentages are drawn from far too small a number of cases to allow of much weight being accredited to them, but from what there is it appears (1) that the average colonial, just arrived in England, has only about 50 per cent. of the natural immunity to the organisms of catarrh prevalent in England that the average English soldier enjoys; (2) that as the result of catarrhal vaccination his immunity can be considerably increased; and (3) that, at any rate for a time, his specific agglutinins to catarrhal organisms exceed in amount those of the average Englishman.

THE Madras Government have decided that lady assistant surgeons shall be employed and granted the same rates of pay and allowances as those drawn by the members of corresponding classes in the male medical service.

THE DIAGNOSIS OF EARLY PHTHISIS.

BY ALFRED FOSTER, M.R.C.S., L.R.C.P. LOND.,
PHYSICIAN, CHRISTCHURCH HOSPITAL, N.Z., ETC.

THIS paper is written from the point of view of a general practitioner. Text-books help very little when the general practitioner is called on to diagnose phthisis without the aid of physical signs. He has only one guide, and that is the effect of the poison of tubercle on the patient.

Having seen the characteristic attacks that occur amongst sanatorium patients during the quiescent stages of their disease, induced by some indiscretion, usually over-exertion, I began to think that if it were possible to recognise this toxæmia it would be possible to diagnose phthisis without physical signs. The indiscreet patient some 24 hours after his indiscretion loses his appetite, feels seedy all over, coughs a little more, and has more or less rise of temperature, and usually tells you he has had an attack of influenza. Now as the attacks occur in patients who are not suffering from secondary infections it seems reasonable to suppose that the poison is tubercle pure and simple.

I would like it to be quite clearly understood that the cases of hæmoptysis, and pleurisy with effusion, both of which are frequently the first indication of the presence of tubercle, are not referred to. These symptoms should be a sufficient guide as to the course to adopt.

The Symptoms of Pulmonary Tuberculosis.

With these reservations and explanations borne in mind the symptoms of pulmonary tuberculosis may be grouped as follows: (1) Cough and expectoration; (2) loss of weight; (3) loss of appetite; (4) rise of temperature. It can safely be taken for granted that no phthisis can exist without these symptoms in the ordinary way. The number of cases in which one or more of the symptoms is absent is very small. Each symptom is open to wide variations in severity.

In any case the picture presented by tuberculous toxæmia is sufficiently regular to enable a diagnosis to be made with a fair degree of accuracy. General seediness and loss of energy are frequent complaints and may accompany the above symptoms, or recurrent influenza is complained of, but these four symptoms are inseparable.

The cough.—This symptom is the only guide to the situation of the focus and varies very greatly in intensity. One case will cough to vomiting, another will not be aware of the cough and inquiries must be made from friends in order to obtain the information. A common history is that of a small bout of coughing on rising in the morning and the expectoration of a small quantity of mucus; in fact, a regular "morning clear-up." The amount of expectoration may be almost negligible and the cough would appear to be more the result of a reflex irritation than from a local cause, such as excessive secretion. Here let me say that the great majority of the cases I have seen originally diagnosed as bronchitis have been cases of tuberculosis with an unusually large amount of bronchial catarrh. My experience lies mainly in Australasia; I have very considerable doubts as to the existence of bronchitis except in the very old and young, where there is no evidence of irritation due to occupation or asthma with an unusual quantity of secretion. What occurs in Europe I do not know, but in this country bronchitis without any broncho-pneumonia is, I believe, unknown.

Loss of weight goes hand-in-hand with *loss of appetite*. There is little evidence that it is due to the wasting produced by some toxæmias, and would appear to be due to the lessened intake of food, plus defective absorption due to the digestion being out of order. The number of patients who seek advice on account of indigestion caused by tubercle is considerable, the indigestion being so great as to mask all the other symptoms. Thus it is a safe rule to follow that patients whose habits of eating, drinking, smoking, and tea-drinking are good, whose teeth are adequate, whose gums are clean and free from suppuration and stumps, and who are not constipated, should always be suspected of phthisis if they are dyspeptic or loth to eat and are losing weight. Short of actual dyspepsia, patients will tell you that, though hungry, on going to table very little satisfies them, and they can eat no more. A patient who "runs down" easily, loses weight quickly and picks up equally quickly on having a holiday, is probably tuberculous. The history of patients whose summer holiday has staved off the onset of phthisis for years is common and characteristic.

The Temperature.

This is the most characteristic feature of the disease. Speaking broadly, there can be no active phthisis without temperature. The characteristic chart is a subnormal temperature in the morning and a slight rise some time between 2 and 6 P.M., the daily variation being from 97° to 99·2° F. or more.

The question arises, What must be considered a rise above normal? Without going into details, it may be taken that a temperature of 99·2° as usually taken in the mouth is pathological. The rise may not occur every day; during the attack of "influenza" it will surely be present, and an attack may be induced by extra exertion and a clear history be given of feverish attacks following some unusual amount of exercise.

I would say here and now, without any reservation whatever, that it is impossible to make a diagnosis of phthisis without the aid of physical signs unless it is possible to have a record of the temperature, preferably every two hours. Demonstration of bacilli in the sputum is the only other unfailing guide. Cases do occur in which phthisis is present without temperature, but these are cases of comparatively long standing and which are in the quiescent stage, such as is induced by sanatorium treatment in quite a number of cases. Sooner or later a relapse occurs and the temperature rises, and there is generally a good deal of cough and expectoration. Such cases, however, are rare, as this is not the time at which the patient seeks advice.

The mouth temperature does not always reveal the truth, so when a case is in doubt a rectal temperature must be taken. There is a general idea abroad that the rectal temperature should be above normal: this is a mistake. The failure of the thermometer to rise in the mouth is due to faulty technique, nothing else. Influences that raise or lower the temperature of the mouth take a very long time, in minutes 30, or more, to pass off.

I would say that the chief bar to early diagnosis of phthisis is the difficulty of obtaining a reliable temperature chart.

Sources of Fallacy in Diagnosis.

There are a few conditions which may simulate tuberculosis, but associated with troubles that are fairly obvious if care is exercised in taking the history: The pre-menstrual rise of temperature in some women; cases of dilated stomach; some cases of anæmia, or latent pyosalpinx. All may show slight rises of temperature during the day. No doubt other causes can be found, but they are not common, and the cause is fairly obvious with careful examination.

It must be borne in mind that phthisis is a disease which remits. Few cases commence and progress without remission to a fatal termination, and a history which points to attacks of tuberculous toxæmia extending over a series of years is quite common. Also, these patients respond most wonderfully to a little help for the time being. I have found that a short stay in hospital with a view to the accurate observation of temperature is quite worth while.

I would like also to point out that tuberculosis officers, though probably much better able to interpret physical signs owing to the constant practice they have, are no more in a position to make a diagnosis where no signs exist than anyone else, unless they are able to secure a record of the temperature. In short, I believe that the solution of the trouble of diagnosis rests in the provision of means whereby the temperature can be recorded, till some reliable and easily applied test for active tuberculosis is discovered.

There is, however, no royal road to the diagnosis of phthisis except by this means, and all the complaints about the inability of the practitioner to make the diagnosis are due to the lack of appreciation that phthisis is a disease of symptoms as well as of signs. If he is provided with the necessary temperature chart the rest is quite simple, as an early phthisis chart is about as characteristic as any chart made.

Conclusion.

Lest anyone should be in doubt as to what I wish to point out, I would like to say that in my experience the case that has definite physical signs is quite an advanced case in most instances, and therefore if we desire to do the best for our patient we must discover his disease before physical signs are present. Given adequate facilities it can be done.

I see by the latest literature arrived since this paper was written that a suitable antigen for a complement deviation test of tuberculosis has been discovered. I hope it will prove reliable on extended trial.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

AN OPERATION FOR THE CURE OF PTERYGIUM.

BY G. F. ALEXANDER, M.B., C.M. EDIN.,
MAJOR, R.A.M.C.; CLIFF MILITARY HOSPITAL, FELIXSTOWE.

THERE being a great tendency for pterygium to return after it has been removed from the cornea, various plans have been devised to prevent this; but while the more simple frequently fail to secure against return the more successful demand considerable incising of the neighbouring conjunctiva and displacement. Considering the advance over the cornea to be due to some *vis a tergo*, I conceived the idea of removing the direction of the growth into a direction which would be harmless if it persisted by inverting the head or part growing over the cornea, under the body, or thickened conjunctiva, and as this is done with the greatest simplicity and in the few cases I have done it has proved entirely satisfactory I consider it merits a trial by those who are frequently called on to treat this disease.

A short snip with scissors is made into the neck or junction of the head and body, just outside the cornea both above and below and the body undermined, keeping close to the sclera, for a distance of several millimetres, which varies with the length of the head we are to invert; the scissors blades closed are then passed under the neck and by a rapid upward jerk made to strip the head from the cornea. The tip of the head is then gripped by strabismus forceps; each end of a thread of No. 2 silk 8 in. long is carried through a needle, and the needles are inserted from without inwards through the head just behind the forceps, one near its upper and the other near its lower border; the needles are then by a director pushed under the body, carried horizontally under it, and made to pierce it from within outwards about 10 mm. from the cornea. The needles being removed the ends of the thread are crossed in a half knot and pulled upon till the head is inverted and the neck about 1 mm. free of the cornea when the knot is completed. If the head is a long one the needles are passed through it about 2 mm. from the neck and then the head within this snipped off vertically by the scissors.

The suture is pulled out after ten days. The narrow bare area of sclerotic outside the cornea soon becomes covered over with epithelium, and no obvious pocket or fold of the conjunctiva is to be seen after a few weeks.

A CASE OF STAPHYLOCOCCUS PHLEBITIS.

BY C. WYNDHAM GITTENS, L.R.C.P. LOND., M.R.C.S.,
HOUSE PHYSICIAN, ADDENBROOKE'S HOSPITAL, CAMBRIDGE; LATE HOUSE PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL, LONDON.

I HAVE not been able to find any account of phlebitis or thrombosis due to the *Staphylococcus aureus*. The history of the case is as follows:—

Patient, aged 58, farm labourer, was admitted on Dec. 23rd, 1917. A week before his left leg began to swell; also history of pain in leg chiefly in front of left thigh and behind left knee, and especially in region of left saphenous opening. No history of rheumatism, gout, or typhoid fever, nor of any local septic condition. On admission the superficial veins of left leg and thigh were more marked than those of right limb; there was soft swelling of whole of left leg and thigh (lymphatics did not seem affected), pain on pressure over left popliteal space and along course of left femoral vein. No thrombosis of superficial veins; no evidence of any endocarditis.

On Jan. 2nd, 1918, he complained of pain in calf of right leg, which was swollen; on careful examination a superficial vein was found to be inflamed and tender. On Jan. 4th whole right leg and thigh were œdematous; right internal saphenous vein and several smaller superficial veins of leg were thrombosed. On this day a bought vaccine of *B. coli* was given, and three (increasing) doses of this vaccine were given at intervals of ten days without any good result.

Patient was admitted with T. 102° F., and he ran septic temperatures until last week in February, when evening rise above normal ceased.

On Jan. 14th there was some suggestion of thrombosis affecting probably the mesenteric veins; abdomen distended, stools offensive and contained blood to the naked eye. This condition passed off after a week; an agglutination test was done; no agglutination to typhoid or to paratyphoid B.

On Jan. 25th T. still very septic; evening rise to 102°, morning T. 100°. Blood culture; *Staphylococcus aureus* grown, and suspected to be accidental, but a second culture showed same result. From this a vaccine was prepared and was given on Feb. 14th when the T. came down to normal for first time. There had been a very definite reaction to the dose of coli vaccine given on evening of Jan. 8th; the T., which had been coming down, rose on Jan. 9th to 103·4°. After that of Feb. 14th (*Staphylococcus aureus*) there were some occasional rises of T., but these gradually subsided, and on and after Feb. 23rd it remained quite normal. The doses of vaccine were gradually increased; definite reactions after third and fourth injections. Blood culture on Feb. 11th showed no growth.

A further complication of interest is that on Feb. 27th a small carbuncle developed on sacrum; this was opened and scraped and gave no trouble. In the pus *Staphylococcus aureus* was present.

Patient gradually improved and was allowed up on March 7th. Still slight œdema of leg. He went home on March 27th wearing elastic stockings.

The temperature strongly suggested a septicæmic condition, and the discovery of a staphylococcus on blood culture made us hope that we had discovered the cause, although we realised how easily the culture may have been contaminated. The result of vaccine treatment was very heartening and proved that the organism was the staphylococcus. I am indebted to Sir Clifford Allbutt for permission to record these notes.

Reviews and Notices of Books.

The Action of Muscles. By W. COLIN MACKENZIE, M.D., F.R.C.S., F.R.S.Edin., Member of the Council of the Anatomical Society of Great Britain and Ireland; formerly Lecturer on Applied Anatomy to the University of Melbourne. Illustrated. London: H. K. Lewis and Co., Ltd. 1918. Pp. xvi.–267. Price 12*s.* 6*d.* net.

Gymnastic Treatment for Joint and Muscle Disabilities. By H. E. DEANE, Brevet-Colonel, R.A.M.C., in charge of War Hospital, Croydon. Illustrated. London: Oxford Press Warehouse. 1918. Pp. 146.

Dr. Colin Mackenzie's original work is a milestone of advance in our knowledge of the function of muscle. While much of it is revolutionary, the author makes out a fair case for his conclusions, which may be briefly summarised by reference to a few concrete examples. There is a physiological law that if a muscle contracts, the antagonist must relax, and we know that supination of the forearm and forcible extension of the elbow are not incompatible. If, then, the biceps were a flexor of the elbow, it would be called upon to relax during the action of the extensor, and, at the same time, contract as a supinator. The conclusion is therefore drawn that the biceps is a pure supinator, does not act as a flexor, and its antagonists are the pronatores teres and quadratus. The antagonist to the triceps is the only true flexor of the elbow—viz., the brachialis anticus. So, too, the old-time controversy as to the rotatory action of the ilio-psoas is done away. It is accredited with the power of flexing the hip only, while the gluteus maximus becomes a pure extensor of this joint. Turning to the fingers, we find that the extensor communis is shown to extend only the metacarpo-phalangeal joints, the lumbricals serving as antagonists; while the proximal interphalangeal joints are flexed by the sublimis, the distal by the profundus, the interossei being given as antagonists to both. The brachio-radialis is shown to be a pure supinator. Evidence in favour of the author's argument is forthcoming as the result of ingenious research in comparative anatomy, and is presented in convincing manner. We anticipate that the bulk of these conclusions, doubtless in somewhat modified form, may later become commonplace knowledge. The author indicates their practical application in muscle rest and re-education, and this will form an attractive study for those engaged in physical therapeutics, and serve to promote independent thought and research rather than the present uncritical absorption of preconceived doctrines. But we find the author a little sanguine in expecting that many of his patients will be ready to carry out the treatment he advocates for 20 minutes four to six times a day. On the one hand, the simplicity of the author's method is a great attraction; we fear, on the other hand, that monotony may be found a serious drawback. But no one who practises physical treatment can afford to ignore his ideas or to dismiss the conclusions untested or the treatment untried.

Colonel H. E. Deane's book should be read and studied as a sequel to Dr. Mackenzie's, although in many respects it is its exact antithesis. Dr. Mackenzie approaches his subject from the standpoint of the comparative anatomist and reaches his conclusions by pure scientific reasoning. His theme is the re-education of muscle. Colonel Deane deals exclusively with the restoration of function. He leaves argument aside, and in one place at least throws science to the winds when he says that the intricacies of muscular association "defy anatomical differentiation." The author expounds two main elementary facts and shows us their application. The first point, so admirably emphasised again and again, is that recovery of function entails voluntary effort; and the second, that it is futile to regard a limb as an entity, but that rather we must consider the whole body when attempting to restore a limb to usefulness. Thus he points out the great value of the leg exercise involved in climbing a rope while training a patient with an arm injury to grip, and of work on the parallel bars should the leg have been injured. The key-note is associated movement, and the plea made is for exercise of every sound muscle in the body, be it strong or feeble. But above all is emphasis laid on what we can only describe as the re-education of volition. Colonel Deane has much to say on the use of mechanical appliances in restoring of function, and he makes out a strong case against it. On the other hand, he acknowledges that in using gymnastics as a remedial agent "a good deal depends on the ingenuity and personal qualities of the instructor." Only those who have had the privilege of seeing Colonel Deane's work at Croydon can realise the great weight these two factors can carry. There will be few, indeed, who can copy, but all who are responsible for the care of the injured should attempt to emulate. The simplicity of the apparatus used by Colonel Deane is a great attraction. The barest gymnasium would be for him fully equipped. The text is well and clearly written and furnishes all that is required as a guide; detail of application can only be attained by experience. The book is well produced and the numerous illustrative cases should prove of great service.

The methods advocated in these two books taken together should provide for the injured of the future a hope of more rapid and more perfect restoration than has been the lot of those who have suffered in the past.

Diseases of the Male Urethra, including Impotence and Sterility. By IRVINE S. KOLL, B.S., M.D., F.A.C.S., Professor of Genito-Urinary Diseases, Post-Graduate Medical School and Hospital, Chicago. London and Philadelphia: W. B. Saunders Co. 1918. Pp. 151. 14*s.*

THIS book comprises a number of sections, including the anatomy of the urethra; the diagnosis and treatment of gonorrhœa and its complications; stricture of the urethra; non-gonorrhœal urethritis; tumours of the urethra; impotence and sterility. The book is conspicuous for its conciseness and the absence of excessive detail in the treatment of the conditions dealt with. It is a little surprising in a work professing to deal fully with the subject of gonorrhœa to find the use of irrigating methods not more fully discussed, but the author has confined himself principally to the methods used in his own clinic. The illustrations are excellent, including many original drawings and coloured urethroscopic pictures. The articles on sterility and impotence are quite short and very useful. The book should prove useful to the practitioner.

Aspects of Death and Correlated Aspects of Life in Art, Epigram, and Poetry. By FREDERICK PARKES WEBER, M.A., M.D.Camb., F.R.C.P. Lond. Third edition, revised and much enlarged. London: T. Fisher Unwin, Ltd., and Bernard Quaritch, Ltd. 1918. Pp. 784. Price 30*s.*

WE reviewed the first and second editions of this informing work, then going under a slightly different title, in THE LANCET of Dec. 17th, 1910, and August 22nd, 1914, respectively, so that we have but little to add as concerns this, the third edition, except that it is nearly five times the size of the first. The increase is due both to large additions to the text and to many more illustrations. The second edition ran to 461 pages. The subject, of course, is almost inexhaustible, and Dr. Weber's book might easily be expanded into a volume the size of the Post Office Directory. In his account of monuments of the "gisant" type—i.e., those in two compartments, showing the deceased both as he appeared in life and as a skeleton or a mouldering corpse—we think that Dr. Weber might have referred to those monuments of which a few examples exist in England—namely, where the dead are represented clothed in a shroud. We can call to mind five such—one in the south choir aisle of St. Paul's Cathedral in memory of Dr. Donne, also interesting as being the only monument which escaped the Great Fire, and the other four in Maidstone Parish Church to the memory of two John Astleys, father and son, and their wives. All four figures are represented as standing in their shrouds. Of punning monuments, to which Dr. Weber refers on p. 7, there is an interesting example in a City church,

either that of St. Katherine Cree or St. Giles', Cripplegate, to a person by name Cage. The monument mainly consists of a heavily barred iron grating, through the bars of which are looking out a number of skulls. Finally, there is one mortuary inscription which Dr. Weber should certainly add to those quoted by him; it is in the cloisters of Winchester College, and runs as follows: "Sub hoc marmore sepultae sunt reliquiae Thomae Welstead, quem calculi impetu atra mors abstulit Non. Mart. 1676. Primus erat in schola, nec, ut speramus, ultimus in caelo, quod pro Oxonio adiit." There is something unconsciously humorous in recording the fact that the boy arrived in Heaven instead of Oxford. After the war we hope that Dr. Weber will issue a fourth edition which shall include, so far as can be done in one volume, the literary aspects of Death.

MONOGRAPHS ON INDUSTRIAL CHEMISTRY.

Organic Compounds of Arsenic and Antimony. By GILBERT T. MORGAN, D.Sc., F.R.S., F.I.C., A.R.C.Sc. Pp. 376. Price 16*s.*

Colour in Relation to Chemical Constitution. By E. R. WATSON, M.A.Cantab., D.Sc. Lond. Pp. 197. 12*s.* 6*d.*

Coal and Its Scientific Uses. By WILLIAM A. BONE, D.Sc., Ph.D., F.R.S. Pp 491. Price 21*s.*

The Applications of Electrolysis in Chemical Industry. By ARTHUR J. HALE, B.Sc., F.I.C. Pp. 148. Price 7*s.* 6*d.* London: Longmans, Green, and Co. 1918.

Dr. Morgan has done medical science good service by writing this interesting survey of the organic compounds of arsenic and antimony which have found such wide application in treatment during recent years. It is medicine, in fact, which has given a stimulus to this branch of research, with the result that many organic compounds of arsenic and antimony of interesting theoretical structure have been prepared. The starting-point was cacodyl, or Cadet's arsenical liquid, produced for the first time, as Dr. Morgan tells us, by Louis Claude Cadet de Gassicourt, as far back as 1760. Great chemists, like Bunsen, Berzelius, and Frankland, saw the significance of the discovery, inasmuch as it meant that an analogue of the alkali oxides had been formed in which the elementary alkali radical is replaced by a compound organic radical. Later followed the elaboration of the organic arsenical medicaments now familiar to us by such names as atoxyl, salvarsan, neosalvarsan, galyl, and others. It was not surprising to find that similar antimony compounds could be prepared, since antimony and arsenic are chemical twins, and so the aromatic stibines were brought into being, and further researches are producing other metallic organic combinations, as, for example, mercurial compounds. Dr. Morgan has written a very interesting monograph, which, besides indicating what British chemical industries can do, should advance our knowledge of the pharmacology of the substances described, and should help us to fathom the relationship of chemical constitution to physiological action.

Dr. Watson's book has also an interest for medicine, since the dyestuffs have a well-known application in medical research and in some cases are employed in therapeutics. The relation between colour and constitution is a fascinating line of practical study, but, as Dr. Watson points out, the quest for the ultimate cause of colour has revealed the great complexity of the problem and has shown the need for further work in this direction. It is obvious that as this relationship is revealed the chemist should be in a position to produce any colour or shade at will. The book is valuable as a record of the facts and developments of research so far as they have gone in an important field of investigation.

It need hardly be said that the publication of Professor Bone's book on "Coal and Its Scientific Uses" is opportune at the present time when we are all forced to consider very seriously the problem of fuel economy in the coming winter. The potential energy of coal has been scandalously wasted in the past through the lack of applied scientific method in employing it for fuel purposes. The directions in which reforms are needed are clearly and most interestingly pointed out by Professor Bone, and the economic lines suggested, by utilising to the full the calorific value of coal, would, when established, mean an asset of inestimable value to the nation. We have read with particular interest the chapters on domestic heating and the smoke nuisance and its abatement, since we have published many practical contributions in connexion with these problems. The book is a valuable addition from the national point of view to the interesting series of monographs, which are ably edited by Sir Edward Thorpe.

Amongst industries to which the war has given a great stimulus come those in which electrolysis has been employed instead of purely chemical methods for the production of certain chemicals. Mr. Hale's book outlines very clearly the electrolytic applications in chemical manufacture which so far have been successfully and economically developed. A very good example, and of interest to medicine, may be quoted of the advantages of the electrolytic method in the production of iodoform. The old method of producing this antiseptic was by the action of iodine upon alcohol in the presence of sodium carbonate, but only 30 per cent. of the iodine by this process goes to form iodoform. By electrolysing alkali iodide, however, in the presence of alcohol the whole of the iodine used goes to form iodoform. Saccharin is produced also electrolytically, but the book is devoted mainly to accounts of the electrolytic production of the great industrial chemicals, chlorine, bleaching powder, caustic soda, white lead, potassium permanganate, and others. There is also an interesting chapter on the electrolytic winning of metals, such as copper, zinc, lead, nickel, and sodium. It is interesting to observe that as far back as 1807 metals were produced by electrolytic methods by Humphry Davy; it has taken us the best part of a century to put this great scientific discovery into practical application. Mr. Hale's work is illuminating on a subject of real importance in industrial affairs.

Treatise on Cystoscopy and Urethroscopy. By Dr. GEORGES LUYS. Translated and edited with additions by ABR. L. WOLBARST. London: Henry Kimpton and Co. 1918. Pp. 386.

As the authors in their preface state, the object of the book is to bring before the profession the results of their efforts as the product of 15 years' practical endoscopy. The book not only deals with the ordinary urethroscopic and cystoscopic methods, which are dealt with in great detail, but also goes into the various applications of these methods and the various uses to which the modern forms of apparatus can be put—e.g., ureteric catheterisation, direct vision cystoscopy, endo-urethral treatment of prostatic hypertrophy, the endo-vesical treatment of bladder tumours, and so forth. Each of these subjects is dealt with in a self-contained chapter, illustrated profusely with pictures and records of cases demonstrating the practical value of the methods and difficulties likely to be met with in carrying them out. In addition there are a large number of coloured drawings representing the appearances of normal and abnormal conditions of the urethra and bladder as seen through the urethroscope and endoscope respectively; these give a rather exaggerated view of the usual appearances seen, still they serve a useful purpose in pointing out the details which it is essential for the endoscopist to recognise. The book is certainly the best that we have seen dealing with this very important subject, both as regards the technique and the difficulties which are likely to be met with. It may be recommended both to the beginner and the expert cystoscopist as a useful addition to his library. It also serves another purpose in stimulating the use of the direct vision endoscope, which should have a more prominent place in the armamentarium of surgeons in this country than it has at the present time.

A Diabetic Manual for the Mutual Use of Doctor and Patient. By ELLIOTT P. JOSLIN, M.D. Philadelphia and New York: Lea and Febiger. 1918. Pp. 187. Price $1.75.

WE have recently reviewed at length (THE LANCET, 1917, ii., 936) Dr. Joslin's comprehensive work on the "Treatment of Diabetes Mellitus." The manual before us aims at securing the intelligent coöperation of the patients, and thus enabling the general practitioner to raise the standard of his treatment to the level of recent discoveries in laboratory and clinic. The manual is arranged in four parts. Part I. the author calls a diabetic primer, giving in untechnical language a rapid survey of the whole subject. Part II. covers the same field in greater detail and outlines the treatment of the severer diabetic. Part III. consists of diet tables and recipes. Part IV. gives simple tests for estimation of sugar and acid bodies. The whole is well arranged and illustrated, and will, we think, well serve the author's aim.

THE LANCET.

LONDON: SATURDAY, OCTOBER 12, 1918.

The Coming Ministry of Health.

AT the meeting of the medical profession held on Oct. 1st in Steinway Hall, having for its object the securing of more adequate representation of the medical profession in Parliament, Dr. CHRISTOPHER ADDISON, the Minister of Reconstruction, alluded to the Bill for the erection of a Ministry of Health in terms suggesting that there was now no doubt that such a measure would be considered at an early date. Dr. ADDISON could not pledge the Government to any particular date; nor, we think, would it be possible for the Government to arrange any programme of domestic legislation whatever to which strict adherence could be expected, having regard to the military and political position of the country, and indeed of the world. The plight and attitude of the Central Empires and our engagements to our Allies in Europe and to the United States of America alike preclude any possible statement that such and such a thing will be certainly done in Parliament by a certain date; there is, however, no reasonable doubt that a Bill will be promoted at the earliest opportunity. The medical profession is consequently feeling its want of representation in the House of Commons, for, in the absence of any public statement as to the provisions of the Bill, there are no channels of discreet information such as most certainly lawyers would be able to employ if a measure were in question of first-class importance, dependent for its working upon the legal profession. It is quite reasonable where a new Bill is concerned that, its general scope and purport having been made clear, no details should emerge until the Bill is read in the House of Commons. But, as a rule, legislation bearing intimately upon the life-work of one section of the community, however entirely public and national its broad bearings are, has been promoted by leaders of that section, or in response to combined work and opinion of that section, and in this way the class most closely interested is aware of what is in store for them. The Ministry of Health Bill has no lineage deriving directly from the medical profession, it is intended to be, more or less in Dr. ADDISON'S words, an "assortment of different departmental responsibilities in health matters," and this assortment has been made in general recognition of the fact that "the most urgent national needs should be made the duty and responsibility of a definite body of men."

We need not here recapitulate the circumstances which have called for such assortment. We all know that six (or more) State Departments at the present moment discharge duties in connexion with the people's health, and we know, also, the particular medical work for which the various departments stand guardian. Those familiar with the medical aspects of legislation in the making will also understand how it has come about that so many different State departments find themselves in possession of a medical bureau and in charge of medical responsibilities. The story here is exactly illustrative of British methods of progress, where the results, though in certain directions they may in their latest developments be found comic, are none the less expressions of very genuine progress. The Poor-law Commissioners of 1834 perceived that ill-health was a principal source of pauperism, and that the removal of the causes of ill-health ought to be a more economical proceeding than the treatment of its consequences; and early public health legislation contained the germ of a national health department. The nation at the time did not appreciate the meaning of the work which was beginning. But medicine, leaping forward from theory to accurate knowledge, became first an official aid and then an inspiriting counsel to further effort; and soon sections of the community became alive to the fact that in various directions they could be relieved of masses of evil, to whose pressure they had hitherto resigned themselves. The public learned that through preventive medicine and sanitation barriers to their health and happiness could be removed which were standing with no better apology than could be found in their antiquity. And as this or that class in the community was aroused it made its claim for relief heard and obtained such remedy as it could get. Schemes of reform initiated in this manner to meet various emergencies were entrusted for their carrying out to various departments of Government and various local authorities. Promptitude was obtained at the time, but there has followed overlapping of jurisdictions, with waste of energy and money, while the resulting confusion has been worse confounded by the creation of new Government Departments and the rearrangement of local administrative machinery. The outcome has been to make the care of the health of the people, as conducted in this country, a medley in which great ideas and brilliant accomplishments are blended with the extravagance and dissipation of strength associated with the want of a central plan. All this has been for many years perfectly obvious to the medical profession, as well as to men and women whose public life has brought them into contact with the truths of our social existence. With them the feeling has been implicit that the health of the people, being a national asset, should have the national supervision of a Government Department. And now the whole nation agrees.

It is to tidy up the muddle that the Bill in the first instance will be promoted by Government, but all medical men look forward to something a great deal more, and a great deal more is expected by the country. For this reason medical men will regard the method in which the new Ministry is kept in touch with modern medicine with interest and even jealousy. The actual administrators of a Ministry of Health must be medical men; the prime authority must have the best services of medicine at call, a desideratum

which is provided for in the workmanlike Scheme for a Ministry of Health put forward by the British Medical Association. We do not think that anyone would suggest otherwise, and if the Ministry is put into possession of a strong Consultative Medical Council from the beginning, chosen on proper lines so that the right men get on this statutory committee for the right reasons, the task of assortment of duties will proceed with much greater ease. For undoubtedly there are difficulties ahead. It is quite easy to laugh at the fact that, for example, the Privy Council is the supreme midwifery authority of the country, and yet it finds itself in that position for perfectly logical reasons; and a representative body of medical men, knowing how the anomaly arose, will know how to end it. There will be difficulty in adjusting the claims of the new Ministry of Health in respect of, for example, the physical welfare of children where the Board of Education is deeply interested, and the sanitary conditions of factories where the Home Office is at present a very judicious authority. The affiliation of medical research to medical practice will be a fundamental necessity in the new legislation. The National Health Insurance Commission at the present moment conducts an admirable Research Bureau on funds raised by itself. The claims of the nation and the rights of the National Insurance Commission can only be adjusted satisfactorily by a thoroughly competent Consultative Medical Council, and the constitution of this body will be the most important part of the forthcoming measure, which does not propose to institute a State medical service.

The Early Diagnosis of Pulmonary Tuberculosis.

EARLY diagnosis is the essential factor in the treatment of pulmonary tuberculosis, but there is still a tendency to attach too great weight to the physical signs alone. We may recall two of the aphorisms of the late Dr. SAMUEL GEE: "Therapeutics must begin before physical signs have developed; for if you wait for physical signs you wait too long"; and "In any case of phthisis the disease is more extensive than the physical signs would seem to indicate."[1] Conversely, extensive physical signs may be left after arrest of the disease, and may be consistent with health and freedom from all activity of the old pulmonary lesions. It is necessary in every case, before making a diagnosis or advising treatment, to review the history, the symptoms, the physical signs, the general condition of the patient, and sometimes his reaction to varying conditions, especially where there is no sputum for examination. We publish in our present issue an admirably suggestive article on this question by Mr. ALFRED FOSTER, of Christchurch, New Zealand, emphasising the importance of these considerations for the general practitioner, to whom, in a large proportion of cases, the opportunity for the early diagnosis of pulmonary tuberculosis is afforded. If the doctor suspects the onset of phthisis before the actual development of unequivocal physical signs, and takes steps to establish the diagnosis by a careful review of all the information available, the patient may be enabled to secure treatment under the most favourable conditions. Mr. FOSTER was impressed by the attacks which occur in sanatorium patients, usually induced by some indiscretion, such as over-exertion. These he describes as associated with loss of appetite, feeling seedy all over, increased cough, and with more or less rise of temperature. Such attacks are sometimes referred to as due to auto-inoculation, and are doubtless the result of the action of the products of the tubercle bacillus. Mr. FOSTER classifies these symptoms as follows: (1) cough and expectoration, (2) loss of weight, (3) loss of appetite, and (4) rise of temperature. He urges that the concurrence of these conditions should lead to a careful examination of the evidence in favour of pulmonary tuberculosis, and in particular that a careful and continuous record of the temperature should be taken. Too often this association of symptoms is attributed to recurrent influenza, or to trivial catarrhal conditions, and thus the opportunity for early diagnosis and treatment may be lost. Such evidences of auto-inoculation, especially if continuous or repeated, should give point to slight and dubious signs or tend to a diagnosis even in the absence of signs. Attacks like this are commonly observed *within* sanatoriums while the patient is under treatment, and Mr. FOSTER thinks their nature should be recognised as suggestive in patients *without* sanatoriums before a diagnosis is established.

[1] Medical Lectures and Aphorisms. By Samuel Gee. London: Smith, Elder. 1902.

A Risky Experiment in Municipal Hygiene.

LAST week London had an opportunity of observing on a large scale what it throws away each day into the streets. Normally this pot-pourri is collected each night by sweepers, and what remains is washed away by watercarts and revolving brushes into the gutters. But for several weeks on end a dispute in regard to a war bonus induced the public servants whose task it is to perform these duties in the Borough of Holborn to stay away from work until their demands were granted on Tuesday last. The spectacle was not an edifying one. In the chief lines of thoroughfare cigarette-boxes, large pieces of paper, and matches constituted the main bulk of the obvious debris, with only a moderate admixture of dried horse dung, inasmuch as the traffic is mainly driven by motor-spirit, gas, or petroleum, and what horse traffic there is is rapid. In the side streets and alleys the amount of horse dung was remarkable, in many places being spread in a continuous adhesive layer over the wood pavement, and on asphalt surfaces, to which it adheres but little, forming a deposit ankle deep in the gutters. Many of the courts and blind alleys were half filled with paper, straw, and other packing material, much of it doubtless carried by the wind into these quiet backwaters. Though the actual stable-yard impression was limited to the Borough itself, dried dung much resembling chaff was carried some distance over its borders, its presence betrayed by an unusual number of feasting pigeons. Fortunately, the weather was favourable for such a bold experiment in municipal hygiene. The air was cool and fresh, and little if any unpleasant odour was present, while the wind was not strong enough to blow clouds of dried dung into the faces of passers-by, but this we owe rather to the clerk of the weather than to the clerk and other authorities of the Borough. There was no obvious accumulation, as might have been expected, of dog dung; presumably the unpleasant habit of urban dog-keeping

is not practised generally in the central district. Nor were the pavements covered with the viscid layer succeeding the shower of sputum described by eye-witnesses as the outward and visible sign of the debouchment of Lancashire workfolk from their factories. The metropolis may have the advantage in this respect.

It will be interesting to watch the health returns of Holborn in comparison with other London boroughs for the dirty week. The first impression of the naive observer may well be some degree of amazement at the apparent smallness of the nuisance which has resulted. And it has even been asked, why fuss? The reply to this laissez-faire attitude is afforded by the accumulated experience of hygiene the world over. Nothing is more certain than that dirt lowers the average health of a community. This is its chief condemnation, and it holds true even though an occasional lapse in a normally clean city cannot be reckoned upon to produce striking epidemics from which to draw sanitary lessons. There were, as a matter of fact, no deaths in the Borough last week from epidemic diarrhœa, although if the weather had been hot and dry it might have been quite otherwise. But even so, simple lessons are there to draw. One is immediate and obvious, and concerns the general public. It is never a tidy habit to throw into the street packing material of any kind, and now when it has its immediate market value it is stupid as well as thoughtless. For the future the riddance of horse traffic from crowded city precincts is seen more than ever to be advisable, and can hardly fail to have some effect in raising the general level of public health.

Annotations.

"Ne quid nimis."

FORMS AND INFORMATION.

PRIMITIVE folk set little value on the written word, and a few reams of paper would suffice their needs for a life-time. Increasing civilisation goes hand-in-hand with the increased use of paper, and the Public Health Acts, and especially the National Insurance Act, have resulted in the medical profession acquiring, if with reluctance, the habit of using abundant printed forms. In respect of the use of paper, indeed, the medical profession may count as a primitive folk, for the large bulk of general practitioners among us make few clinical records, their prescriptions are brief, and letter-writing is almost a lost habit for lack of leisure time. The consumption of paper by the official runs to enormous dimensions, as double entry has taken the place of single, and as for convenience of office routine documents have become quadrupled and quintupled. In commercial life the use of paper to push the sale of articles may be said to be roughly inversely proportionate to their value. It is therefore a satisfaction to find a recent edict of the Local Government Board making a clean sweep of many official documents when they attain a sufficient age. Six-year-old treasurers' books, cash books, and petty cash books, inventories, collectors' books, and a host of others, the existence of which was hardly suspected, may now be sold to the waste-paper merchant with great relief both to office and paper-supply. Notifications of diseases, births, and the like, may be pulped on the expiration of 12 months from the completion of the audit of the last entry contained in the records, or in the case of other documents, "as may be considered desirable." For our part we cannot see how a notification of infectious disease can possibly serve any useful purpose after it has been entered up by the medical officer of health on his spot-map or schedule. And the same must surely apply in some measure to a host of other documents. In the case of Poor-law documents, public vaccinators' registers, medical relief lists and indices may now be released when over six years old, but not the registers of vaccination officers. Medical officers' record cards, temperature charts, and dietary books may all go sooner. This more rapid turn-over seems to us entirely of a salutary nature. Might not, in fact, a small amount of paper in rapid circulation between town hall and pulper serve every possible purpose? The hoarding of forms is the result of sloth and want of enterprise on the part of those who should abstract from them the essential information for current use. Hoarded forms are not only waste of paper, but they are actually harmful by appearing to convey information which, in fact, they simply bury. Perhaps the shortage of paper will last long enough for the form hoarding habit to disappear and for its place to be taken by rational abstracting and indexing.

PTERYGIUM.

AMONG the many obscure points which puzzle the ophthalmic surgeon the condition of pterygium presents special difficulties; its origin, its development, and its tendency to relapse and recurrence, all offer problems which are still to solve. Much has been written of its causation, but without bringing to light the solution of the riddle. Some writers lay great stress on the influence of race; others deny any racial influence and consider the difference of incidence to be climatic only. Certainly, the disease is not common in England; equally certainly, it is comparatively common in some climates; it is said to be endemic in Madeira. Nor is its mode of development much clearer; the theory, originated many years ago, that the fold of conjunctiva is pulled over the cornea by the gradual inward progress of an ulcer at the tip of the fold, seems definitely disproved; but what process it is which leads to the destruction of Bowman's membrane, and the adhesion of the conjunctiva to the cornea, is still discussed. Certainly, the position of the folds in the line of the palpebral fissure leads one to think that irritation probably has some part in the production of pterygia; but occasionally they are found in other meridia; again, what part, if any, in the causation is played by the pinguecula? Is there any real share, or is the supposed relation nothing but the coincidence of position? All these points await solution; and in this country the material is so scanty that we have done little to throw light on the subject. The arrival of a large number of men from the uttermost parts of the earth during the last few years has increased this material, and has offered opportunities for operation greater than we have hitherto had. In operation the chief point has been to overcome the tendency to recurrence; for this reason the pterygium has been transplanted in various directions; but it has been considered an essential to cover the region of the sclerotic, laid bare by the removal of the growth, by means of conjunctival

flaps taken from healthy conjunctiva. In the note which is published elsewhere in our present issue Major G. F. Alexander suggests a method which is very like the methods of Galezowski and of Bettman in the manner of dealing with the pterygium by rolling the head, or part near the cornea, under the body. This process Bettman called "subvolution" or "subinvolution," but both these operators were careful to cover the raw surface. Galezowski and Bettman laid it down that the presence of the conjunctiva against the sclerotic tended to prevent a relapse. Major Alexander has not found recurrence in those cases in which he has left a raw surface. Unfortunately, he does not tell us the condition of the pterygia on which he operated. Although all pterygia are pathologically the same—at least this is the received opinion—they are not all the same in their clinical behaviour; some are much more liable to relapse and recurrence than others. If Major Alexander's cases were all of the form called clinically p. crassum, his observation and results are most important. If, on the other hand, the cases were p. tenue, it does not follow that he would be equally successful with the other form.

POISONING FROM EXHAUST GAS.

Two years ago attention was drawn[1] at a French Army medical reunion to the risk from exhaust gas in motor ambulances. Fatal cases of poisoning had been observed where the exhaust-pipe of the motor was leaky, the post-mortem lesions suggesting carbon monoxide poisoning. In a recent number of the *Journal of the American Medical Association* Dr. C. W. H. Hitchcock has added another instance occurring in civilian life. A chauffeur entered a small close garage about noon to do some work on the car. About two hours later a maid sent to call him could hear the engine running but got no answer. She produced a key and unlocked the door. The man was found in the seat of the car dead, the engine still running, and the door and windows closed. There was a pinkish red discolouration all over the body. The internal organs were found normal and the blood saturated 58 per cent. with CO. In another case a man, aged 30 years, went to his garage on a cold morning, started the motor, and returned to the house. After a few minutes he went back to the garage to oil the car. While doing so he smelt something very sweet and had a desire to laugh. He saw yellow flashes before his eyes and felt weak at the knees. His first thought was to sit down on the running board, but he decided to return to the house. When just outside the garage he felt a sudden throbbing of the temples and extreme weakness. An hour later his wife found him lying in the snow apparently asleep. He could be roused, but staggered, and could not walk alone. He was put to bed and went to sleep. After an hour he awoke, complaining of dizziness, and was unable to walk. He complained of a throbbing headache, and talked incoherently. He apparently recovered and returned to work on the following day, but he talked incoherently and was unable to remember dates and other simple facts. When he returned home in the evening he remarked that he could not get any sense out of the evening paper which he was trying to read. During the night severe headache and cough began. A fatal attack of pneumonia followed. As we pointed out when the French cases occurred, the explanation is not quite simple. Exhaust gas ordinarily contains a minimal quantity of carbon monoxide, and it would require 600 c.cm. of CO to saturate the three litres of blood in the vessels of the average man. But whatever the precise toxic agent may be it is evident that neither garage nor ambulance should be without means of ventilation.

[1] THE LANCET, 1917, i., 161.

THE INTERDEPENDENCE OF THE SYMPATHETIC AND CENTRAL NERVOUS SYSTEMS.

THE current number of *Brain* contains a paper by Dr. David Orr and Dr. R. G. Rows that is of interest rather for its suggestiveness than for its record of actual research. The work of these two observers has been instrumental in distinguishing clearly two types of morbid invasion of the nervous system, the lymphogenous and the hæmatogenous. In the case of the former the lesion results from the involvement of the ascending lymph paths of cranial or spinal nerves, and the phenomena which arise are essentially those of a primary inflammation of the fixed tissues. In the case of the latter, experiment has shown that invasion of the nervous system by the blood stream brings about coagulation necrosis of cells, degeneration of fibres, œdema, dilatation of the vessels, and hyaline thrombosis, with practically no inflammatory reaction. In the cord these lesions are found almost entirely, in the first instance, round the cord margin and on either side of the median septum of the posterior columns. Lymphogenous infection causes lesions which spread by direct continuity; hæmatogenous infection appears to result in unexpectedly limited lesions both in brain and cord—the brain lesions are almost always, if not always, confined to the cortex, cornu ammonis, and amygdaloid nucleus. These areas, both in brain and cord, derive their blood-supply from the vessels of the pia arachnoid. This peculiar and special anatomical distribution, to the total exclusion of the central areas, suggests that the theory of a general intoxication via the blood stream requires considerable qualification. In other words, some other factor than mere blood dissemination is necessary to explain this curious limitation of blood intoxication in both divisions of the central nervous system. Dr. Orr and Dr. Rows believe that evidence can be advanced in favour of the view that the sympathetic nervous mechanism may be an important factor in determining at which points a toxin circulating in the blood shall exercise its primary action upon the central nervous system. They base their argument on a consideration of certain cases of spinal cord change due to toxic conditions of the blood stream—e.g., in visceral cancer, Addison's disease, and subacute combined degeneration of the cord associated with severe or pernicious anæmia. If the spinal cord is examined in these cases changes are found not of an inflammatory but of a degenerative nature, mainly in the posterior columns in the vicinity of the septum, and also towards the periphery of the cord; in subacute combined degeneration the changes are, as a rule, much more profound and widespread, although their character is the same. Further, considered vertically, these alterations occur chiefly in the lower cervical, dorsal, and upper lumbar segments. The authors next point out the difficulty of explaining non-systematised yet peculiarly limited lesions by the action of a general morbid agent, and suggest that this cord localisation can be correlated with the spinal distribution of the thoracico-lumbar sympathetic system. As for the cervical lesions,

the sympathetic afferent fibres of the lower cervical cord come from the stellate ganglion, which consists in a fusion of the first two or three thoracic ganglia. The suggestion, then, is that the cord lesions of the conditions above enumerated are due to some interference with the thoracico-lumbar sympathetic "reflex," caused possibly by pathological stimuli, or by the absence of substances which maintain its balance. This results in dilatation of the pial vessels, whose permeability is thus increased, whence diffusion of noxious substances and resulting degeneration.

PARAFFINED GAUZE.

THE introduction of gauze which has been smeared or soaked in paraffin, either soft or liquid, is comparatively recent; yet this form of dressing has several merits, and there can be no doubt that it will be more widely employed in future. Attention is drawn to it in the article on Gunshot Wounds of Joints, by Captain J. Campbell, the first part of which appears in the present issue of THE LANCET. He points out that among its merits are these: it exerts pressure, and so restrains hæmorrhage; it does not furnish a moist medium in which micro-organisms can flourish; it does not tend to adhere to the surface of newly formed granulations, and when it is removed the surface does not tend to bleed as when moist gauze is employed. There is a further advantage to which Captain Campbell does not allude, and that is that as it does not tend to adhere to the granulating surface its removal does not cause nearly so much pain as does the removal of a piece of gauze which has been moistened with a watery fluid. Some surgeons prefer that the gauze should be prepared by soaking in sterilised liquid paraffin, while others think that better results are obtained by using soft paraffin. Further experience may show which is the better method of preparation.

THE WATER-SUPPLY OF THE COUNTRY.

IT was stated at a meeting of the Municipal Waterworks Association last week that a system of national control of watersheds was urgently needed in order to secure to the community a fair division of the country's supplies. Many of the large watersheds had already been secured and some authorities had come to the end of their present resources and were looking afield for an enhanced supply. Big cities like Glasgow, Birmingham, and Manchester soon found that their supplies drawn from lake districts were hardly adequate to the needs of a population growing rapidly year by year, and various schemes from time to time have been considered with the view of increasing the quantity of water. It is a fact that in many thickly populated parts of the country nearly all the most accessible areas are now taken up, and the suggestion has been made that the Government should exercise some control over the nation's water-supply in order to secure for each town and district an adequate quantity of water based upon the population at a reasonable cost. In connexion with this subject Sir Alexander Houston, the Director of Water Examination, Metropolitan Water Board, has written a useful little guide dealing with rural water-supplies and their purification.[1] As he points out, despite the enormous improvements in our public water-supplies, not only as regards quality and quantity of water, but in respect of its availability to isolated communities, there remains a large but scattered population, whose only source of a primary necessity of life is rain-water or the water from shallow wells. The utilisation of rain-water is largely Sir Alexander Houston's theme, and he gives directions as to how this is best done with simple methods of purification and sterilisation. The one difficulty with rain-water appears to be to render it palatable and free from sooty taste. Slow filtration through charcoal gives the best results.

LOCAL CANCER RESEARCH: REPORT OF THE MEDICAL OFFICER OF HEALTH OF WOOLWICH.

Dr. Sydney Davies, medical officer of health of Woolwich, has for some years been conducting research in regard to cancer, and in his annual report of 1917, just available, he states that the period had the lowest cancer death-rate for five years; the reduction being greater in men. As compared with 1913, and previous years, in men there had been a decrease under carcinoma of the throat and intestines; and in both men and women an increase of cancer of the stomach. The special inquiry into the habits of persons suffering and dying from cancer since 1912 was continued. The scope of this and the standards taken are shown in previous annual reports. The following table gives the parts affected for males and females:—

Parts Affected.

Seat of primary disease.	Male.	Female.	Total.
Face, mouth, jaw, and tongue	35	7	42
Pharynx, œsophagus, larynx, and neck	37	6	43
Stomach and pylorus	29	22	51
Intestines (excluding rectum)	16	14	30
Rectum and anus	17	17	34
Liver	9	4	13
Breasts	—	8	8
Uterus	—	4	4
All other...	11	2	13
Total	154	84	238

Further analysis of the cases shows:—

Seventy-four of the patients were stated to be excessive users of alcohol, 22 took the standard quantity, and 127 below the standard. There were thus 33 per cent. of excessive alcohol-drinkers. 91 smoked excessively, 18 consumed an average quantity of tobacco, and 113 below the average, giving 41 per cent. of excessive smokers. 65 were excessive tea-drinkers, 89 moderate, and 54 small tea-drinkers, giving 31 per cent. of excessive tea drinkers. 99 were large eaters, 72 moderate, and 48 small eaters, giving 45 per cent. large eaters. 71 were large meat-eaters, 86 moderate, and 57 small meat-eaters, giving 33 per cent. of large meat-eaters. 130 had a daily action of the bowels and 44 suffered from constipation, giving 75 per cent. of persons with a regular action.

Control or non-cancer cases.—These cases may be compared with those obtained for 218 persons of similar or greater age, living under similar circumstances, who did not die of cancer. Of these, 37 took alcohol excessively, 24 took the standard quantity, and 157 below the standard, giving 17 per cent. excessive drinkers. 46 smoked excessively, 19 in moderation, and 157 were non-smokers or slight smokers, giving 21 per cent. of excessive smokers. 66 took tea excessively, 96 in moderate amount, and 48 were small tea-drinkers, giving 31 per cent. of excessive tea-drinkers. 28 were large eaters, 22 moderate, and 13 small, giving 44 per cent. of large eaters. 19 were large meat-eaters, 9 moderate, and 36 small, giving 30 per cent. large meat-eaters. 166 had a regular daily action of the bowels, and 26 suffered from constipation, giving 14 per cent. of constipation.

It will be seen that, comparing persons who suffer from cancer with those living at advanced ages, or who died at advanced ages through other causes,

the great differences are as to habits with respect to alcohol, smoking, and the action of the bowels. Cancerous persons had 33 per cent. of excessive alcohol users, 41 per cent. excessive smokers, 31 per cent. excessive tea-drinkers, 45 per cent. large eaters, 33 per cent. large meat-eaters, and 25 per cent. of constipation. Non-cancerous persons, living to a greater age, had 17 per cent. of excessive alcohol users, 21 per cent. excessive smokers, 31 per cent. excessive tea-drinkers, 44 per cent. large eaters, 30 per cent. large meat-eaters, and 16 per cent. of constipation. These differences are still more marked with respect to alcohol and smoking, if only those who died from *cancer of the mouth and throat* are considered. Of 103 persons dying from cancer of the lips, tongue, jaws, fauces, larynx, œsophagus, and cervical glands, 46 (or 45 per cent.) took alcohol excessively, while 73 (or 71 per cent.) smoked excessively. Twenty-eight of these smoked chiefly a clay pipe, 27 a briar, 3 cigarettes, and 3 cigars. There were only 5 out of the 37 cases of cancer of the mouth and tongue who did not smoke; 3 of these had bad teeth. Among the non-cancer cases all the smokers smoked pipes (42 clay and 25 briar, and 5 both), except 2 who smoked cigarettes. Of 161 cases with cancer of other parts than the mouth and throat 39 (or 24 per cent.) took alcohol excessively, and 36 (or 22 per cent.) smoked excessively. It would appear, then, that both alcohol and smoking (especially alcohol) have some general effect in promoting cancer, but chiefly exert their injurious influence locally. This is shown also as regards alcohol by the figures given below for cancer of the stomach, which occupies an intermediate position. Of the 103 cases of cancer of the mouth and throat, 28 (or 27 per cent.) were excessive tea-drinkers. Tea-drinking does not seem to be specially injurious locally or generally as far as cancer is concerned. If the injurious effect of smoking were chiefly due to the local effect of heat one would have expected excessive drinking of hot tea to have had a similar result. Of 13 cases of *cancer of the stomach*, 8 were large eaters and 2 were large meat-eaters; and of 52 cases 16 (or 31 per cent.) were excessive alcohol-drinkers. As regards *cancer of the bowels*, out of 59 persons dying from cancer of the intestines, 32 had a regular daily action, and 26—i.e., 44 per cent.—had constipation. The above results in tabular form are as follows:—

—	All cancer cases.	Cancer of mouth and throat.	Cancer of other parts.	Control cases (non-cancer).
	Per cent.	Per cent.	Per cent.	Per cent.
Excessive alcohol-drinkers..	33	45	24	17
,, smokers	41	71	22	21
,, tea-drinkers ...	31	27	34	31
Large eaters	45	—	—	44
,, meat-eaters	33	—	—	30
Constipation	25	—	—	16

Thus constipation seems to predispose to cancer of the bowels.

MEDICAL SOCIETY OF LONDON.—A general meeting of this society will be held at 11, Chandos-street, W., at 8 P.M., on Monday, Oct. 14th, when the treasurer's report and balance-sheet will be presented, and the new officers will commence their duties. The first ordinary meeting of the session will follow at 8.30 P.M., when the incoming President, Major Arthur Francis Voelcker, R.A.M.C., will deliver the opening address, to be followed by a demonstration on "Degeneration in Art, Music, Science and Literature," by Dr. Theo. B. Hyslop.

TRENCH FEVER:

A CRITICAL ANALYSIS OF THE REPORT OF THE AMERICAN COMMISSION.[1]

BY SIR WILLIAM OSLER, BART., M.D.

I.—*Introduction.*

THIS handsome volume of 446 pages represents the work of a commission appointed at the suggestion of the Medical Research Committee of the American Red Cross, the official sanction for which dates from Jan. 11th, 1918. A Trench Fever Committee, consisting of Major H. Cushing, Major H. F. Swift, and Major R. P. Strong, was appointed, to which was added Major J. W. McNee, R.A.M.C., as an honorary member. It was arranged with the authorities that the work should be carried on at a stationary hospital of the B.E.F., near enough to the line to catch cases of trench fever in the very early stages. The members of the Commission were Major R. P. Strong, Major E. L. Opie, Major H. F. Swift, Captain W. J. MacNeal, Captain W. Baetjer, and Captain A. M. Pappenheimer, all of the Medical Reserve Corps, A.E.F., and Captain A. D. Peacock, R.A.M.C., as entomologist, and subsequently attached First Lieutenant Rapport, A.E.F. From the start there was active coöperation between the British and American authorities, and in framing the plan of research the Commission had the benefit of the advice of Colonel Leishman, General Bradford, General Herringham, and Colonel Beveridge.

The suggested problems for investigation were the method of the transmission of the disease, and the infectious properties of the blood, with a view of repeating and confirming the previous work of Major McNee. Since, so far as was known, the disease is not transmissible to animals, the next problem was to secure volunteers for the experiments. This was arranged by General Ireland, chief surgeon of the A.E.F., with the Commander-in-Chief, with the proviso that each volunteer was to have the nature of the experiments fully explained, and that he should sign a paper expressing his willingness to undergo the experiment. Sixty volunteers were selected out of hundreds who applied, and subsequently 14 were added. All underwent a careful examination to exclude any unfit, and then bacteriological examinations were made of the blood, urine, and fæces. Four-hourly temperature charts were taken, semi-weekly inspections were made of the bodies and clothing, followed by a bath, and the clothing was sterilised once a week. The men of the experimental detachment were segregated from the British hospital personnel and patients. As it was realised that the time was limited before the spring offensive began the experiments were planned to be completed within approximately two months' time. Major Swift took charge of the clinical work, Major Opie the bacteriological investigations, Captain Pappenheimer the serological studies, Captain Baetjer the inoculations, Captain MacNeal and Captain Peacock conducted the louse investigations, while Major Strong directed and superintended the work and prepared the report for publication. On March 27th, for military reasons, it became necessary to evacuate the trench fever detachment from the hospital where the work had been progressing for two months. The necessary experiments to complete the investigation were made at the American Red Cross Hospital, Neuilly.

The study of the problem of transmission involved the investigation of the infectious properties of the blood, sputum, urine, and fæces, the differentiation of the disease from the forms of enteric fever, and particularly the agglutination curves of inoculated subjects. 103 different human experiments were carried out in connexion with the transmission of the disease and its cause, of which 28 were in connexion with blood transmission, 38 transmission by lice, 16 in connexion with the urine, fæces, and sputum, and 21 in connexion with the virus. The disease has been produced experimentally by different methods in 62 instances.

II.—*Story of the Disease.*

In the autumn of 1915, at a C.C.S., Dr. G. H. Hunt, of Guy's Hospital, showed the writer cases of fever characterised by short paroxysms, with a tendency to recurrence.

[1] Trench Fever: Report of Commission, Medical Research Committee, American Red Cross. At the Oxford University Press. 1918.

Major J. H. P. Graham gave the first description in THE LANCET (Sept. 25th, 1915), and other papers followed by G. H. Hunt and A. C. Rankin (THE LANCET, 1915, ii., 1133) and J. W. McNee, E. H. Brunt, and A. Renshaw (*Brit. Med. Jour.*, 1916, i., 225). Sir Wilmot Herringham early recognised that it was a disease unlike any of the ordinary forms. We then began to have cases admitted to the hospitals in this country with the diagnosis of trench fever, characterised by short paroxysms of pyrexia and a curious complication—viz., painful shins. The disease came to be widely recognised on the Western front in both Allied armies, in Germany (where it was called Wolhynian fever, His-Werner or five-day fever), in Salonika by Hunt, in Italy and in Mesopotamia by Coombs. It became very frequent and one of the principal causes of sickness. Captain E. R. Grieveson stated (THE LANCET, 1917, ii., 84) that trench fever formed 40 per cent. of his hospital evacuations and at one time 60 per cent. of all cases of sickness. McNee (loc. cit.) states that it is the most serious disabling disease of the soldier in the Western armies, and with scabies constituted fully 90 per cent. of all cases of sickness in one of the British armies. A majority of the cases labelled P.U.O. are believed to be due to it. The question of the relation of trench fever to other diseases is discussed in Chapter II. by Major Strong, whose large experience in the tropics gives weight to his opinion that it cannot be definitely identified with any hitherto-described disease.

The *incubation period* has been proved to vary from 14 to 30 days, though if a large dose of the virus is acquired the period may be shorter.

"*Symptoms and course.*—During the incubation period slight prodromata, as headache and pain in the limbs and slight fever, are occasionally noted. The most characteristic clinical features of trench fever are the sudden onset, accompanied by headache, dizziness, pain in the legs and back and behind the eyeballs, particularly when moved, nystagmus on turning the eyes completely sideways, injection of the conjunctivæ, and a sharp rise of temperature to 103° or 104° F. The fever in over one-half of the cases subsequently assumes a relapsing character. Enlargement of the spleen and the appearance of small erythematous spots or papules occur in from 70 to 80 per cent. of the cases. The erythematous spots are observed particularly over the chest, back, and abdomen. They are usually not raised above the surface of the skin, are pink in colour, disappear on pressure, and generally measure about two to four mm., although sometimes they may measure from four to six mm. in diameter. Occasionally the rash is distinctly papular in character. In number the spots vary from several to one or two hundred. They often disappear in less than 24 hours after their appearance, and they may occur early in the fever, as on the second or third days, or be first observed just prior to or during a relapse. While no one of these symptoms given above can be regarded as characteristic or constant, the presence of several or all of them usually serves to make the diagnosis of trench fever accurate. The urine often shows a trace of albumin, but evidence of true nephritis is not present. The leucocyte count is very variable. There is frequently a leucocytosis, and the leucocytes may rise at the time of the relapse. In other cases, however, the count may be normal or there may be a leucopenia.

The fever does not always follow a definite type, but may consist of, first, a short attack, lasting for about a week, with sometimes, but not always, after a few days, a single short rise; second, a more prolonged initial fever, sometimes lasting for six or seven weeks, with relapses not distinctly marked; and, third, a more regularly relapsing fever, with more or less definite normal intervals, lasting from five to seven days. Many variations of these types of fever are also seen, and in some of the patients there may be a long fever lasting from 40 to 60 or more days with only very slight remissions." (p. 16.)

The number of relapses varies: three to five periods are common, and there may be as many as seven. Recovery follows in all cases.

III.—*Specific Nature.*

Chapters III. and IV. deal with this question. The first point to determine was whether there was any evidence of infection with the enteric group of organisms. The examination of the blood, urine, and fæces of spontaneous and experimentally produced trench fever by methods adopted to demonstrate typhoid and paratyphoid bacilli were uniformly negative. An extensive study of the agglutination tests gave no support to the view that trench fever was a modified enteric infection. The details of this study, as given in Chapter IX., are most interesting. The titre of the serum in individuals inoculated against the enteric group was in a few instances modified by the trench fever, but in neither a constant nor a characteristic way. This is the first opportunity there has been for a careful bacteriological study of so many cases of a pure strain of trench fever produced by inoculation through successive generations, and the authors hope these investigations will terminate the controversy regarding the relationship of the disease to the enteric group. Examinations of the blood were also made to exclude other known forms of infection. Anaerobic cultures were studied by the dark-field microscope for spirochætes with negative results. No definite micro-organisms were discovered by any of the known means of examination.

McNee, Brunt, and Renshaw first demonstrated that the disease was infectious and transmissible by the blood. Seven men were inoculated with the whole blood, and all developed the disease. One inoculated with clear serum remained healthy, one inoculated with hæmoglobin-tinted serum developed the disease; of two cases inoculated with washed corpuscles one did and one did not, while none were infected who received inoculations with filtered serum. These crucial experiments of McNee and his colleagues made in 1916 received ample confirmation by the American Commission in February, 1918. Thirty-four of the volunteers who had been carefully studied in every possible way were inoculated either with blood or some constituent element of blood taken from trench fever cases in the febrile stages, of whom 23 contracted the disease. The results agree in a number of points with those obtained by McNee and his colleagues. The blood is always infective in the early stages. They found the incubation period to be from 6 to 22 days, the American observers from 5 to 20.

"They, however, consider that the organism of trench fever was intracorpuscular and not free in the plasma or serum. They, however, performed only one experiment with plasma, and though the disease was produced in an individual inoculated with it, they concluded that it was infective only because hæmolysis of red cells had occurred, the plasma being tinged with hæmoglobin. In another case they produced the disease with hæmoglobin-tinted serum and drew the same conclusion, as in another case they failed to produce the disease with clear serum. We also failed in one case to produce the disease with clear centrifuged serum. In relation to the production of the disease with washed corpuscles, McNee, Brunt, and Renshaw performed two inoculations. One of the men developed trench fever, the other did not. We obtained positive results with washed blood corpuscles in three instances, and have already discussed the significance of them (p. 27) and pointed out that apparently the virus remained so intimately mixed with the corpuscles in these experiments as not to be separated by washing with saline solution. Our conclusions, based on the results of our experiments, differ from those of McNee and his colleagues in that we believe that the virus or organism of trench fever is present particularly in the fluid portion of the blood, and is not contained within the blood corpuscles themselves" (p. 28).

Extensive experiments were made to determine the filterable qualities of the virus. The original must be consulted for details, but three positive experiments, of five performed, demonstrated that at least in one stage of development the virus of trench fever is filterable and ultramicroscopic.

"It was found that the virus resists a temperature of 60° C. moist heat for 30 minutes, and is fully virulent after such treatment, but is killed by a temperature of 70° C. moist heat for 30 minutes. Obviously, therefore, a temperature of 55° C. for 30 minutes, which destroys the louse *Pediculus humanus* and its ova, does not suffice to destroy the virus of trench fever which may be present on the underclothing of trench fever patients. The details concerning these experiments are given in Chapter XII., p. 284."

The authors conclude that the outlook regarding a method of vaccination against the disease does not appear particularly hopeful.

IV.—*Etiology and Mode of Transmission.*

In Chapter V., after a review of previous investigations, the conclusion is reached that the causative organism of the disease remains undiscovered. The blood is invariably infective in the early stages. The virus was not found in the fæces, and attempts at inoculation failed; but it was present in the urine, and sometimes in the mixed sputum and saliva, as shown by successful inoculations. Chapter V. deals with the mode of transmission, in which the authors demonstrate conclusively the rôle played by the louse. Various suggestions had been made as to the part played by lice, mosquitoes, fleas, rats, and mice, and the literature is fully considered. Weldon and Davies, in 1917, made the first experiments with lice, and on Feb. 3rd in THE LANCET reported a successful case of transmission. There had arisen a strong feeling that the disease was lice-borne, supported actively by Hurst, Hunt and McNee, Grieveson and others, but adequate proof was not forthcoming. The Commission undertook the investigation of the problem.

"*Transmission experiments.*—Thirty-eight healthy men from the 82 volunteers referred to in Chapters I. and IV. were employed in the experiments relating to the transmission of the disease by *Pediculus humanus*, var. *corporis*, as well as a number of other healthy volunteers who were employed as controls. Twenty-six of the men were employed in the first group of louse experiments and 12 in the second. ..... In the first group of experiments the object particularly in view was to demonstrate whether *Pediculus humanus*, var. *corporis*, does or does not transmit trench fever. In the second group the experiments were performed particularly with the idea of giving further evidence of, first, whether the louse may transmit the disease in nature by its bite alone, as well as by its bite when living under artificial conditions; second, the length of time the louse is infective in this respect; and, third, the infectivity of filtrates of suspensions of louse excrement known to contain the virus before being filtered."

In a majority of the experiments a pure-bred strain of lice obtained from the Lister Institute was used. A plan was adopted by which the lice lived as naturally as possible upon the experimental subject, confined in a chamber or cell in which they bred and laid ova.

"*Transmission by infestation.*—Of the 26 men employed in the first group of experiments 20 were exposed in this manner to lice that had bitten trench fever cases in the febrile stages of the disease, while four others were exposed for the same or a longer period of time to normal, uninfected lice which had only fed upon healthy individuals. After a period of over three months, in order to show whether the men who had been exposed to the normal lice were or were not naturally immune to trench fever, three of them were subsequently exposed by other methods to trench fever infection. All of them contracted the disease. Of the 20 men in the first group and six in the second group who were exposed to lice that had fed upon cases of trench fever, 20, or 76 per cent., developed this disease. On the other hand, the two exposed to many hundred lice newly hatched from eggs laid by lice which had fed on trench fever cases did not contract the disease. Thus no evidence was obtained of hereditary transmission of the virus of trench fever in the louse. In the three instances in which lice taken from the clothing of trench fever cases were employed for infection, two of the individuals exposed to such lice contracted the disease."

Experiments were also successful in showing that the louse may transmit trench fever by the bite alone through the normal skin.

In five instances lice which had not been in contact with a case of trench fever for from 48 to 60 hours were shown to be capable of causing trench fever in healthy men. The lice may transmit the disease after they have been taken away from a case of trench fever for as long a time as 13 days, which points to a multiplication of the virus, or an intermediate cycle of the organism within the louse.

The next question was whether the disease was spread in any other way than by biting. Infection may follow the rubbing into the scratched or abraded skin the crushed louse or the contents of the alimentary canal; but whether the virus is introduced in material from the salivary glands, or the cœlomic fluid or the material from the alimentary canal was not determined. Eight of the volunteers free from lice and living with and sleeping under exactly similar conditions to the other volunteers who were contracting and had contracted trench fever from the infected lice confined upon them in covered cells remained healthy, as did four other control volunteers living under the same conditions, except that normal lice were confined upon them.

Chapters VII.–XII. give full details of the blood transmission experiments, the bacteriological studies, the agglutination reactions, the lice-feeding experiments, the filterability and thermal death-point of the virus, and the infectivity of the excreta.

Clinicians will turn with interest to Chapter XIII., in which the features of the experimentally induced disease are described. This part of the work has been prepared in great detail, and the full reports, with temperature charts, of 80 cases are given, two of which are reproduced in the note at the end of this article. Practically the artificially and naturally acquired disease present the same features, now too well known to describe again; but one or two points may be emphasised. Nystagmus was found in 85 per cent. of the patients, associated, it is thought, with the general muscular weakness and not a specific feature. A macular rash was present in a majority of the cases, chiefly on the chest and abdomen, and the spots may recur with each "spiky" relapse. This percentage of cases, a rash 50 to 70, is much higher than we have seen in the relapses in this country. The spleen was enlarged in 85 per cent. Shin pains and tenderness were not so common or so severe in the artificially induced disease. The effort syndrome, so marked a sequel of the natural disease, was not met with.

V.—*Conclusions of the Commission.*

The following conclusions were reached by the Commission:—

"1. That trench fever is a specific, infectious disease; that it is not a modified form of typhoid or paratyphoid fever, and is not related, from an etiological standpoint, to these diseases.

2. That the organism causing the disease is a resistant filterable virus.

3. That the virus causing trench fever is present particularly in the plasma of the blood of trench fever cases, and that such plasma will produce the disease on inoculation into healthy individuals.

4. That the disease is transmitted naturally by the louse *Pediculus humanus*, Linn., var. *corporis*, and that this is the important and common means of transmission; that the louse may transmit the disease by its bite alone, the usual manner of infection, or the disease may be produced artificially by scarifying the skin and rubbing in a small amount of the infected louse excrement.

5. That a man may be entirely free from lice at the time he develops trench fever, the louse that infected him having left him some time previously as its host, and that the louse need only remain upon the individual for a short period of time in order to infect him.

6. That the virus of trench fever is also sometimes present in the urine of trench fever cases, and occasionally in the sputum, and that the disease may be produced in man by the introduction of the virus in the urine or sputum through the scarified or otherwise abraded skin.

7. That since the urine and sometimes the sputum of trench fever patients are infective, these should be sterilised in order to avoid the possibility of accidental infection from them.

8. That in order to prevent trench fever or limit its spread, and thus save man-power for the armies, greater efforts must be made to keep soldiers in general from infestation with lice.

On account of the great importance of the matter the following sanitary regulations are advised: Exceedingly great care should be taken to completely disinfest all patients as soon as practicable, and particularly upon their entering the hospital. Patients on entrance should be carefully bathed, and subsequently sponged with alcohol. Their clothing and blankets should be removed, and, whether or not lice or ova are found upon them, should be carefully sterilised by moist heat at a temperature not below 70° Centigrade for half an hour, since it is possible for the virus to be still present on the clothing. It should be borne in mind that a man with trench fever may be entirely free from lice at the time that he develops symptoms of the disease. Trench fever patients should at all times be carefully protected from louse infestation, and inspection of them for lice should be made daily. They should be treated in separate wards. As the urine contains the virus and is infective it should be sterilised during the active stages of the disease. Sputum cups should be provided for patients, and any expectorated sputum and saliva from them sterilised. Officers should regard the systematic destruction of lice as one of the most urgent of their duties, and should exercise every effort to prevent louse infestation among soldiers and to see that any of them infested with lice are promptly disinfested and their clothing sterilised."

Remarks.

One of the shocks of the great war has been that lousiness and the itch have had such an innings. We had become clean enough, at least in this country and America, to forget the enormous capabilities of the louse. The fate of armies has been decided through the devastations of diseases transmitted through it. The truth is that the "sparrow hawks of Montagu College," as Rabelais called lice, have always been terrible pests. In a MS. note-book of John Locke is a memorandum of the placards on the walls of streets of Paris giving directions against the prevailing lousiness. Many persons have a curious tolerance of their presence. An Austrian soldier under my care at the Johns Hopkins Hospital assured us that he was never in the best of health unless he was verminous. There is a famous seventeenth-century tractate, *Laus pediculi* (addressed Ad Conscriptores Mendicorum Patres), which begins: "Sacrum morbum esse opinionem vere positer ac eliganter Patres Mendicorum, ab antiquis proditum memoriæ est." The idea of harmlessness was widespread, and is expressed in the Beggar's Song in Izaak Walton's "Compleat Angler":—

> A hundred herds of black and white
> Upon our gowns securely feed,
> And yet if any dare us bite,
> He dies therefore as sure as creed.

Burns puts a truer feeling in his famous poem "To a Louse"—

> Ye ugly, creepin', blastit wonner,
> Detested, shunn'd by saunt an' sinner.

The reports of the English and American Commissions should help enforce effective regulations—not in warfare always easy to carry out—against the "crowlin ferlie's" that have done so much damage.

In supplementing in this way the work of the Army the American Red Cross has done a splendid service. The report is a good illustration of the value of team-work. Without the active coöperation of all the members, so laborious an undertaking could not have been accomplished in so short a time. We may join heartily in the thanks which the Commission offers to the men who endured so patiently the many trials of the experiment. To Major Strong and his able colleagues we may offer our warmest congratulations; and our thanks are due to Mr. Frederick Hall, of the Clarendon Press, for the prompt production of a beautiful volume.

AMERICAN RED CROSS REPORT ON TRENCH FEVER.

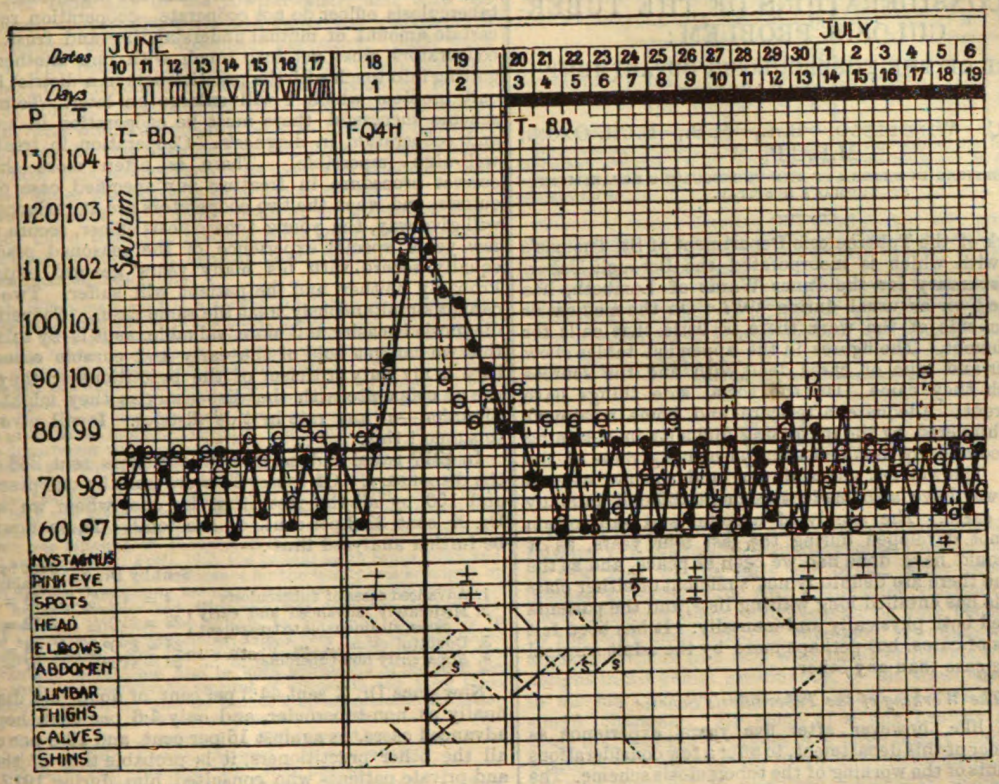
SAMPLE CASE REPORTS (WITH CHARTS).

Out of the 80 case reports presented in detail in the volume under notice we have selected for reproduction two which are fairly typical of the research as a whole, giving in the first only the actual notes of the case.

Key to Charts.

The temperature is indicated by solid dots and continuous line; the pulse-rate by circles and broken line; spleen palpable by the black stripe at the top of the chart; nystagmus, pink eye, and spots by a + or ± in the respective file. Under the various regions of the body a sloping line \ indicates pain, / tenderness, and X both, dots showing less severity. T = temperature. B.D. = twice a day. Q4H = every four hours. P.X. = physical examination.

CHART 1.



(For Key to Charts see previous column.)

Fig. 1 is the chart of a sergeant in the American Expeditionary Force who voluntarily submitted to inoculation with trench-fever-infected material. On Feb. 25th he was injected intravenously with filtered plasma from a well-marked case of trench fever in a man of 21 on the second day. He was then under observation until June 10th without evidence of trench fever. On June 10th his arm was scarified, and combined dried sputum sediment from four cases of trench fever was rubbed in. The result is summarised as follows:—

Local reaction slight. Incubation period, eight days. Prodromata: none. Onset sudden, with dizziness and pain on rotation of eyes. Course: initial two-day bout of fever, with pains and corresponding tenderness. Very slight cough and a few râles accompanied this. On the ninth day a small crop of spots; no fever or symptoms. On the twelfth day, headache and fever of 99·2° F. On the thirteenth day, a small crop of spots. On the fifteenth day, fever of 99·1° F. and slight lumbar and shin tenderness. Spleen continuously palpable from third to nineteenth day. A mild course. NOTES.—*June 10th:* Arm scarified and dried sputum sediment rubbed in. *June 18th*, 7 P.M.: At 2 P.M. began to feel dizzy. Dizziness intermittently during the afternoon. No headache. Pain on rotation of eyes. Slight soreness of muscles above crest of ilium. Does not feel sick, but nevertheless does not feel entirely well. No sore throat. Very occasional dry cough. No appetite for supper. Has felt chilly for past hour (has been in bed). P.X.: Pink eye +. Nystagmus 0 (pain on deviation of eyes). Tongue: Slight furry brown coat. Lungs clear. Abdomen negative. Spots +. Spleen 0. Slight tenderness left shin. Looks toxic. *June 19th:* During night felt chilly. Did not sleep well on account of headache. No appetite for breakfast. Slight pains in thighs and calves. Still looks toxic. Tenderness as charted. The spots have practically disappeared. Musical râles throughout both lungs. *June 20th:* Much better this morning; cough almost gone, never marked. Lungs are clear. It would appear that the mild respiratory symptoms are simply a part of the general picture. The spleen is easily palpable this morning. The condition looks like trench fever. *June 26th:* Since last note has felt quite well. With the character of the first bout of fever a relapse might be expected if the condition is trench fever. The spleen is still distinctly palpable, and this morning a few spots appeared. *June 27th:* Feels quite well. The spots, which were quite distinct yesterday morning, had disappeared at 5 P.M. There are none this morning. *June 30th:* Yesterday evening had "tired" feeling in calves and shins, not amounting to pain. Headache. Appetite poor. This morning feels well. P.X.: A few spots. Spleen persists. Tenderness: Lumbar and left shin, slight. *July 1st:* Feels well. Spots gone. *July 2nd:* Slight fever last night, unaccompanied by symptoms except a "tired" feeling in back of neck. *July 4th:* Headache last night. *July 7th:* Spleen not palpable to-day. *July 18th:* Has felt well since last note. Now up all day. P.X. negative.

CHART 2.

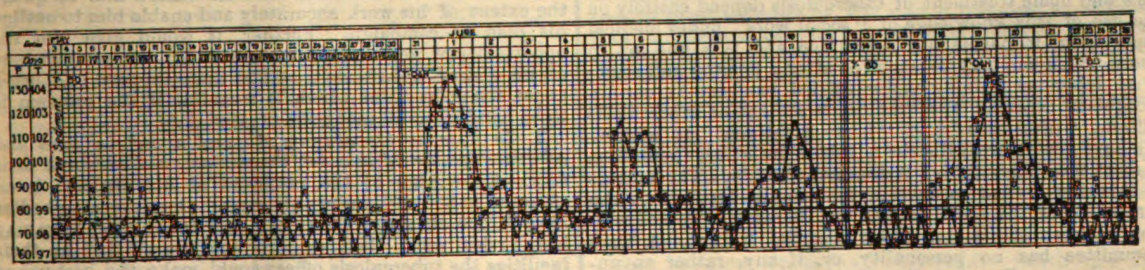


Fig. 2 is the chart of a private soldier, aged 20, inoculated with urine sediment from another experimental case of trench fever, and therefore at second remove from the spontaneous disease. The summary is as follows:—

May 3rd: Arm scarified and urine sediment from No. 30 (collected on second day of disease) applied. *May 13th:* Repeated with urine of the eighth, tenth, eleventh, and twelfth days of the same case. No. 30 had contracted the disease following similar urine sediment inoculation. Incubation period 28 or 18 days. Prodromata: Slight headache the day of onset. Onset sudden, with a chill, followed by severe headache. Course: Four two-day cycles of fever, the peaks of the first three separated by four-day intervals, while the last one occurred nine days after the third, as though one relapse had been skipped. All were marked by severe prostration, but by a dearth of pain and tenderness.

SOME CONSIDERATIONS OF THE TUBERCULOSIS PROBLEM:

REPORT OF THE TUBERCULOSIS DEPARTMENT, ST. THOMAS'S HOSPITAL.

BY R. C. WINGFIELD, B.A., M.B., B.CH. OXON., M.R.C.P.,

MEDICAL OFFICER IN CHARGE OF THE TUBERCULOSIS DEPARTMENT, ST. THOMAS'S HOSPITAL.

THE work of the Tuberculosis Department of St. Thomas's Hospital, with which is incorporated the Borough Tuberculosis Dispensary for the Inner Wards of Lambeth, has been carried on as usual during 1917. On the medical or therapeutic side of the work there is little that calls for special comment. The figures in the appended tables show the number and type of cases dealt with and the sources from which they came. On the social side things have been different. Adequate after-care and home treatment have been hindered by the increasing difficulty in obtaining suitable food and by the decreasing purchasing value of the sovereign. The worries, uncertainties, and sorrows attendant on the war have also made treatment difficult in many individual cases. The supply of hospital and sanatorium beds has not developed during the last four years, as it probably would have done had we been at peace, and at the present time there are definitely not sufficient of either class of bed. This has entailed long waiting lists, and the patients have suffered both physically and mentally. It has been felt by all types of cases, but perhaps more by the adult surgical tuberculosis case than any other.

The Working of the Tuberculosis Scheme.

I should like, however, after five years' experience as medical officer of this department, to offer a few considerations on some points of the working of the tuberculosis scheme. The scheme is that in each district practitioners shall treat their panel and private patients for tuberculosis, and that in the district there shall be a tuberculosis dispensary with its tuberculosis officer, whose services they can demand, for help in diagnosis and advice and help in the treatment of these cases. That this tuberculosis officer shall supervise the treatment and that the practitioner and the tuberculosis officer shall coöperate in this work. This scheme does not, and cannot, work satisfactorily. The reasons are many, but I intend to deal with only two.

First, the general practitioner cannot treat his cases of tuberculosis. Second, he and the tuberculosis officer do not (and perhaps cannot) satisfactorily coöperate. This looks, at first sight, like a vicious attack on the general practitioner, but it is not so, as I hope to be able to show.

To take the first point: The satisfactory treatment of tuberculosis needs expert medical knowledge, and also expert knowledge of what I may call "social work among the working classes," and very few people in England have this double expert knowledge—certainly not the overworked general practitioner—and had he got it, the tremendous amount of pure medical work which he has to get through in the 24 hours would prevent him from using his knowledge of "social work" on any but a very few of his cases. After-care and home treatment of tuberculosis depend entirely on the use of this knowledge of "social work" under medical supervision, it has its own technique and is a fine art in itself, which can only be acquired after a lengthy and somewhat laborious training under skilled teachers at certain recognised centres; and medical treatment of tuberculosis without "after-care" and "home treatment" is useless. We have now in every district a Tuberculosis Care Committee to meet this difficulty, but it does not meet it. The success of this side of the treatment of tuberculosis depends on the personality of the social worker and the very close coöperation between the doctor and the social worker. A Care Committee has no personality, or, if any, rather an unpleasant one. The Care Committee meets once a week or once a fortnight, and the whole aspect of a difficult case may have changed once or twice during that time; it never sees the general practitioner, and only very occasionally communicates with him, this is not close coöperation. Hence my contention that the general practitioner cannot treat his cases of tuberculosis

As to the second point—viz., that the practitioner and the tuberculosis officer do not coöperate—coöperation requires a certain amount of mutual understanding and trust, the two coöperators must get into touch with one another. This getting into touch with the practitioners in a district is a difficult problem which I will enlarge on later. To make the scheme successful there must be coöperation in treatment and coöperation in diagnosis. Coöperation in treatment is well-nigh impossible. There is often more than one correct procedure in treating any specified case of tuberculosis, and when the two coöperators are at variance, which will give way, the young tuberculosis officer, secure with his few years' special experience, or the seasoned practitioner equally secure with his many years' general experience? Probably neither, and the patient will suffer. Two doctors cannot simultaneously treat the same case. Coöperation in diagnosis is easier and more valuable, as it is by this means that we can get hold of the early and curable cases. And here is my only criticism of the practitioners: they do not use or coöperate with the dispensary as they might in this direction—at any rate in this district. I will give figures to support this.

In 1917 panel and private practitioners sent 268 cases to the dispensary. Of these, 88 were sent by one practitioner and 180 by all the rest; that is, one, whom we will call Dr. X, sent 32·8 per cent. of the total. These figures may be further analysed thus:—

	Sent by Dr. X.	Sent by all other practitioners.
1. Advanced cases of tuberculosis ...	4 = 4·6%	33 = 18·3%
2. Moderately advanced and early cases, all amenable to treatment	22 = 25·0%	72 = 40·0%
3. Doubtful cases	23 = 25·0%	48 = 26·6%
4. Apparently non-tubercular	39 = 44·3%	27 = 15·0%

Now since Dr. X sent 44·3 per cent. of doubtfuls, diagnosed finally as non-tubercular, and only 4·6 per cent. hopelessly advanced cases, as against 15 per cent. and 18·3 per cent. of all the other practitioners, it is probable that of the panel and private patients who consulted him during 1917 Dr. X, making full and proper use of the tuberculosis dispensary, missed or failed to adequately deal with very few treatable cases of tuberculosis—and if he did, seeing the high percentage of "doubtfuls" and "apparently non-tuberculars" sent by him, the onus rests very properly with the tuberculosis officer.

Suggested Modifications of Tuberculosis Scheme.

So much for destructive criticism of the tuberculosis scheme as it stands to-day; I should like to add a few points of a constructive nature.

1. *That the tuberculosis officer should be given certain facilities (to be enumerated below) and be held responsible for the health of his district as regards tuberculosis.*—By this means his work could be judged by his results, and it would provide more incentive to thorough work and scope for personal initiative than is at present experienced by this full-time public official, who in his present position feels that he is unable to do more than nibble at the edge of a large area of useful work that is waiting to be done, a position so disheartening that sustained and conscientious effort is very difficult.

2. *To have all cases of tuberculosis in the district notified direct to him.*—This innovation would allow him to gauge the extent of his work accurately and enable him to outline his plan of campaign. Further, it would give him the opportunity of getting into touch with all the practitioners of his district, gain their trust and their support, and bring about the coöperation which is essential if the problem is to be handled at all along the present lines.

3. *To have at his absolute disposal a certain fixed and adequate number of hospital, sanatorium, and advanced home beds.*—Knowledge of the resources at his disposal is an essential in the conduct of this work. Our governing bodies have it, but they can never tell how many cases they may have to deal with—their scope is too large. Had he their facilities the tuberculosis officer could make the best use of these beds and their value to his district would tremendously increase. At present he does not know how many or what type of case he may have to deal with, nor what, if any, beds he will have for their treatment.

4. *To have attached to his dispensary a whole-time social worker with an adequate staff.*—The working man who has once completely gone down with tuberculosis can seldom if

ever be got back to and kept at suitable work without help. This applies especially to the town-dweller, and here the social worker, coöperating with, and under the guidance of, the tuberculosis officer is absolutely necessary. Such work needs: (*a*) The personal factor. Sympathy, discipline, and leadership. (*b*) Thorough knowledge and training in the work. (*c*) Money. State aid for after-care would be money well spent and would save many beds at institutions in the long run. As in the case of the facilities of the tuberculosis officer this money should be fixed and adequate, and completely under the control of the social worker.

This work cannot be properly done by an after-care committee any more than the medical side could be done by a committee of doctors. A typical case, one of many, will help to emphasise this point.

In March, 1914, a man, aged 33, attended the tuberculosis dispensary of the hospital on the advice of his panel doctor. He was found to be suffering from phthisis, and sanatorium treatment was recommended. His former employment had been that of a machine-hand in a mill, a very unsuitable and dusty occupation. The family consisted of a wife and child aged 11. When her husband ceased to be a wage-earner, the wife had gone to work, but as she was only able to earn about 12*s.* a week and her food, it was necessary that some help should be given to the family. Through the coöperation of the lady almoner's department with the local office of the Charity Organisation Society this was done, and finally the patient went to a sanatorium under the National Insurance Act in May of 1914 and was discharged in October of the same year fit for light work only. Financial help was given from the sources already alluded to until the patient got a job as auxiliary postman for a few weeks at Christmas-time. This was followed in January, 1915, by a post as timekeeper in a small restaurant. In April, 1915, the patient again broke down and had to give up his work, and assistance for the family was arranged by the Social Service Department for many months. Towards the end of the year he had another bad turn and was admitted to hospital. Until September, 1916, he was unable to work and constantly in receipt of assistance. In September, 1916, a very light job was found for him, which he still holds. His duties are light, and offer the very great advantage of enabling him to work practically in the open air. Although there is a considerable amount of disease in the lung there is no reason to anticipate that he cannot keep his present occupation for an indefinite period. This case may be tabulated thus:—

March, 1914–Dec., 1914—9 mths. Ill. Help needed.
Dec., 1914–April, 1915—4 mths. At work. No help needed.
April, 1915–Sept., 1916—16 mths. Ill. Help needed.
Sept., 1916–present—20 mths. Well. At work; permanent conditions.

Remembering that this case is that of a self-respecting working man, it will be readily granted that he could not have been tided over these 25 months of illness without the personal encouragement, sympathy, and conscientious endeavour of a whole-time social worker.

5. *The tuberculosis officer to actually treat all cases should they so desire, and to coöperate with the practitioner, if possible, in the treatment of those who did not wish for dispensary treatment.*—The necessity for the tuberculosis officer to do the actual treatment at the dispensary is my great point. He has the social worker behind him and he should, if properly qualified, know best how to treat the disease. It saves work and frees the practitioner for his other important duties and prevents the evils of coöperative treatment and overlapping.

These are a few points which I think would help to improve our present tuberculosis scheme. Different difficulties come to different tuberculosis officers in different districts, and I have tried here to enlarge upon some of mine and to suggest remedies for them in bare outline.

Total Number of Cases Dealt With.

Obituary.

ROBERT DONALD KEITH, M.A., M.D. ABERD.

Dr. Robert Donald Keith, formerly principal of King Edward VII. Medical School, Singapore, died at Turriff, N.B., on Oct. 2nd, at the early age of 41, after prolonged and intense suffering borne with astonishing fortitude. Even in these troublous times, when sensations have become blunted by the daily destruction of manhood, his death will come as a genuine shock to a very wide circle of friends who found a delight in his genial personality, in his transparent honesty in all his dealings with his fellow creatures, and in his simple character. He came of a fine healthy agricultural stock and was the youngest of a large family, notable among whom is Professor Arthur Keith, the distinguished anatomist. He was educated at Aberdeen University, passing through arts and medicine with distinction. Subsequently, as Carnegie Fellow, he studied pathology and bacteriology in Leipsic, Tübingen, and the London Hospital. He had originally intended to specialise in some branch of clinical medicine, but at about the age of 30 he was elected teacher of anatomy and physiology in the Medical School at Singapore, where he spent 10 years. He soon made his presence felt, and was raised to the important positions of Principal of the Medical School, lecturer on clinical medicine, consulting physician to Tan Tock Seng's Hospital, and his opinion was widely sought by the English residents in the Straits Settlements. At the outbreak of war he became captain and officer commanding the Singapore Field Ambulance, medical officer in charge of the Military Hospital, Singapore, and actively participated in quelling the mutiny in that city in the early days of the war. There is reason to believe that overwork and devotion to duty told on a constitution which had not been robust for some years and which had been undermined by residence in the tropics. On arriving home about the end of 1916 he was seriously ill and underwent an operation, which afforded such relief that he was able to take a military appointment of importance in a large hospital for cases of shell-shock. Some months ago, however, his health completely broke down. Despite great suffering he was able to complete an excellent book on clinical case-taking which is likely to be widely appreciated by medical students. Dr. Keith is survived by his wife and three sons.

MEDICAL MAGISTRATES.—Sir Arthur William May, K.C.B., of St. Tudy, Cornwall, formerly Director-General, Medical Department, R.N., and Mr. Thomas Mitchell Bonar, M.B., C.M. Glasg., D.P.H. Bristol, of Truro, have been placed on the Commission of the Peace for the County of Cornwall.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—The following entrance scholarships have been awarded:—University Scholarship of 50 guineas: R. Y. Paton, Trinity College, Cambridge. Open Scholarships: £100, R. M. Fry, Merchant Taylors' School; £50, D. Levi, Marylebone Grammar School. Palmer Scholarship: £25, R. W. Scarff, City of London School. Epsom Scholarship: £52 10*s.*, J. A. Walker, Epsom College.

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue:—

Killed.

Major T. F. P. Breen, R.A.M.C., was educated at Stonyhurst and at Trinity College, Dublin, and qualified in 1912. After holding an appointment at the Mater Misericordiæ Hospital, Dublin, he joined the R.A.M.C., and went to France on the outbreak of war.

Major C. McN. McCormack, M.C., R.A.M.C., qualified at Belfast in 1914. The award of the M.C. was recorded in THE LANCET of Sept. 30th, 1916, p. 620.

Capt. J. T. Kirkland, M.C., R.A.M.C., qualified at Glasgow in 1909, and held appointments at the Maternity and Women's Hospital, and at the Royal Infirmary, Glasgow. The award of the M.C. was recorded in THE LANCET of Jan. 22nd, 1916, p. 215.

Lieut.-Col. F. H. Bradley, D.S.O., R.A.M.C., qualified at Edinburgh in 1906, and joined the R.A.M.C. in 1910. The award of the D.S.O. was recorded in THE LANCET of Jan. 12th, 1918, p. 78.

Died of Wounds.

Temp. Surg. F. P. Pocock, D.S.O., M.C., R.N., was a student at Westminster Hospital, and qualified in 1913. Prior to joining the Royal Navy he was in practice at Ealing. He took part in the operations against Zeebrugge and Ostend in April this year, for which he was awarded the D.S.O. (THE LANCET, August 3rd, 1918, p. 155).

Capt. G. M. Cowper, R.A.M.C., was educated at Cambridge University and at St. Bartholomew's Hospital, London, and qualified in 1914. He joined up on the outbreak of war, and was latterly attached to 35th Field Ambulance.

Lieut. W. L. Dandridge, R.A.M.C., attached 103rd Field Ambulance, qualified in November, 1917, and joined up early in the present year.

Lieut. M. J. O'Flynn, R.A.M.C., attached to the Northampton Regiment, qualified in Ireland in 1903, and held appointments at the Wolverhampton Eye Infirmary and at the Salisbury Hospital. Prior to joining up he was in practice at Neath, Glamorganshire.

Died.

Capt. J. Wood, R.A.M.C.

Wounded.

Lieut. H. A. Chodak, R.A.M.C., attached London Regt.
Lieut. F. Cameron, R.A.M.C., attached Welsh Regiment.
Major A. R. Dale, M.C., R.A.M.C.
Major C. B. Davies, M.C., R.A.M.C.
Capt. R. H. Fleming, R.A.M.C., attached R. Sussex Regt.
Capt. H. K. Ward, M.C., R.A.M.C., attd. Northampton Regt.
Capt. E. C. Bowden, R.A.M.C., attached London Regiment.
Capt. N. F. Graham, R.A.M.C., attached London Regiment.
Capt. W. H. Johnston, R.A.M.C., attached R.F.A.
Capt. D. R. Wark, Canadian A.M.C.
Capt. G. A. C. Gordon, R.A.M.C.
Capt. D. Barlow, M.C., Australian A.M.C.
Capt. R. Goulden, Canadian A.M.C.
Capt. C. L. Driscoll, R.A.M.C., attd. R. Welsh Fusiliers.
Major W. Vickers, Australian A.M.C.
Capt. J. E. Barry, Canadian A.M.C.
Capt. H. M. Cameron, Canadian A.M.C.
Lieut.-Col. A. S. Donaldson, D.S.O., Canadian A.M.C.
Capt. A. H. Veitch, Canadian A.M.C.
Capt. M. K. Acheson, M.C., R.A.M.C.
Major T. J. Kelly, M.C., R.A.M.C.
Capt. R. J. Snider, R.A.M.C.
Lieut. G. P. W. Staunton, R.A.M.C.
Capt. W. C. Morgan, Canadian A.M.C.

Injured.

Surg. J. S. L. Roberts, R.N.

Missing.

Capt. A. La B. Clark, R.A.M.C.
Capt. W. C. D. Wilson, R.A.M.C.

Previously reported Missing, now reported Prisoner in German Hands.

Major E. J. Tilbury, R.A.M.C.

THE NEW SURGEON-GENERAL, U.S.A.—Major-General Merrite W. Ireland, who has been nominated to succeed Major-General W. C. Gorgas as Surgeon-General of the United States Medical Corps, is still a young man, having been born in 1867, and is 13 years junior to his predecessor. He graduated in 1890 at Detroit College, Michigan, and in the following year at Jefferson Medical College, Philadelphia. In the early days of the war General Ireland was stationed at Fort Sam Houston, Texas.

OBITUARY OF THE WAR.

JAMES STEEL, M.B., CH.B. GLASG.,

MILITARY CROSS;
CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain Steel, who met his death in France on Sept. 2nd, at the age of 25 years, was only son of D. F. Steel, of Dennistoun, Glasgow. Educated at Whitehill School and Glasgow University, he graduated M.B., Ch.B. in 1916, during his final year acting as resident assistant at the Glasgow Eastern Hospital. On leaving the University he received a commission in the R.A.M.C. and was sent to France, where he was promoted Captain after one year's service. In March of the present year, while serving with the Royal Sussex Regiment, he was awarded the Military Cross for conspicuous gallantry and devotion to duty. The award ran:—

"This officer was one of the few regimental medical officers who were with their unit during the whole period of withdrawal. He was indefatigable in dressing the wounded, often under fire, and when he had to move invariably assisted himself in evacuating the worst cases. Although twice wounded himself, he refused to leave his work, except to have his wounds dressed."

A few days before his death he was transferred to the Somerset Light Infantry, and it was while marching with his regiment to the fighting line that he was killed by a shell.

An old medical friend writes: "His scholastic and University career, coupled with his attractive and engaging personality, assured him success in the profession he had chosen and loved so well."

CHARLES DEVEREUX MARSHALL, F.R.C.S. ENG.,

STAFF SURGEON, ROYAL NAVY.

WE can now supplement the bare account of Staff Surgeon C. D. Marshall which appeared in THE LANCET of Sept. 28th with a portrait of this officer taken from a group and enlarged, and with some personal details given by his friends. He was at one time sub-editor of the *Ophthalmoscope* and his own writings cover a wide field, including papers on glioma of the retina, sarooma of the uveal tract, and researches on colour vision in collaboration with Dr. F. Edridge-Green. A fleet-surgeon writes of him: "The death of Staff Surgeon Marshall will bring a feeling of bereavement to his former shipmates. I have never met any man who so completely won the esteem and affection of everyone in his ship. It was to Marshall whom we naturally turned when down on our luck. His religious convictions influenced his whole life; he was a tender-hearted doctor; he loved his life at sea; he was father and mother to every youngster on board and he had a very real influence on all who knew him. On that ghastly night following the landing at Gallipoli he heard that an attempt was to be made to evacuate the wounded from the *River Clyde*, which was at the time under musketry fire from both sides, and though he had been at work continuously for 18 hours and was quite exhausted he at once volunteered to go, and went."

GRAHAM ROBERTSON COWIE, B.M., B.CH. OXON.,

CAPTAIN, SOUTH AFRICAN MEDICAL CORPS.

Captain G. R. Cowie, who died of wounds on Sept. 3rd at the age of 27, was elder son of J. Cowie, formerly of Johannesburg. He was educated at the Lyceum, Hanover, and Loretto School, Musselburgh, going on to University College, Oxford, where he won the Welsh memorial prize in 1911, and graduated two years later. He rowed in Eights and Torpids, played Rugby football and hockey for his college, and was a member of the University Corps of King Edward's Horse. At the outbreak of war he re-enlisted in that regiment; in December, 1914, obtained a commission in the Royal Field Artillery, and went out to the Western front in May, 1915. He was mentioned in despatches for his services at the battle of Loos. Returning to England in January, 1916, to complete his medical studies at the Middlesex Hospital, he graduated last year B.M., B.Ch. Oxon., and M.R.C.S. Eng., and was given a commission in the South African Medical Corps, and returning to the Western front attached to the 1st S.A. General Hospital. At his own desire he was transferred to a South African Brigade R.G.A. as M.O., and was so engaged when he was wounded on Sept. 1st by a shell, dying of his wounds two days later. His commanding officer, writing of his loss, adds: "Captain Cowie was always loved by his patients, and anything that he could do for them was never too much trouble," and the dean of his hospital records the good influence exerted by him in everything connected with the medical school.

ALFRED ROBINSON MACMULLEN, M.R.C.S. ENG.,

SURGEON, ROYAL NAVY.

Surgeon A. R. MacMullen, who died of wounds in France on Sept. 7th at the age of 29 years, was third son of the late William F. MacMullen, of Rockcliffe, Cork. He was educated at Clifton College and Caius College, Cambridge, going on from there to the London Hospital, where he was acting as house surgeon at the outbreak of war. He volunteered at once for the Navy and served first with the Royal Naval armoured cars in German West Africa and East Africa for a period of nearly two years, during which time he was awarded the Distinguished Service Cross for conspicuous bravery in searching for and rescuing a severely wounded officer under heavy fire. In August, 1918, he was appointed surgeon to the Royal Naval Division serving in France, and had only been out one month when he was dangerously wounded on Sept. 4th and died of his wounds three days later.

Captain JOHN SIDNEY WILSON, A.A.M.C., who died of wounds on August 9th, was educated at the Church of England Grammar School, Sydney, N.S.W., and entered the medical school there in March, 1912, graduating M.B., Ch.M. four years later. As a student he took a keen interest in field sports, and had considerable success in rowing in University and college races. After qualifying he was for six months R.M.O. at the South Sydney Hospital, before joining the Australian Imperial Force in November, 1916. He was attached to various training units in the United Kingdom, and then joined a field ambulance in France, performing the duties of bearer captain from Nov. 13th, 1917, until August 9th last, when he was hit by fragments of shell while supervising the evacuation of wounded, and died from shock the same afternoon. Captain Wilson's character impressed all with whom he came in contact, and his loss is felt by every officer in the unit.

Major JOHN CLARENCE WELLS, A.A.M.C., who was killed on the same day as Captain Wilson, was educated at St. Peter's Collegiate School, Adelaide, graduating in medicine at the University two years prior to the outbreak of war. He then held the appointment of resident surgeon at the Adelaide Hospital for 18 months. In January, 1915, he enlisted in the Australian Imperial Force, serving with the 1st Australian General Hospital, and later with the 1st Light Horse Regiment as regimental M.O. in Egypt and Gallipoli. In April of the present year he was transferred to an infantry battalion as R.M.O., and served with this unit on the Somme. On the second day of the advance from Villers-Bretonneux he was wounded by a shell fragment and died on the same day. A brother officer who knew him well writes of Major Wells's studious and retiring disposition and of the fine impression made by his gallant and soldierly conduct.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported:—

Second Lieut. R. L. I. Arnott, Indian Infantry, killed in action, younger son of Col. J. Arnott, I.M.S., of Edinburgh and Wyselty, Dumfriesshire.
Major M. Staveley, M.C., R.F.A., died of wounds, second son of the late Mr. W. H. C. Staveley, F.R.C.S.
Major T. F. P. Breen, R.A.M.C., killed in action, elder son of the late Inspector-General T. J. Breen, R.N.
Lieut. E. G. Shepherd, Canadian Infantry, killed in action, only son of Dr. F. J. Shepherd, of Montreal, Canada.
Second Lieut. R. F. Higgs, Queen's Regiment, killed in action, youngest son of Dr. A. W. Higgs, of Chelsea, London, S.W.
Lieut. C. O'N. Daunt, South Lancashire Regiment, attached R.A.F., killed in action, younger surviving son of Dr. F. E. H. Daunt, of Clapham, London, S.W.

EXEMPTION FOR MEDICAL PRACTITIONERS.

Cases have occurred in which applications for the grant of exemption to a duly qualified medical practitioner have been made to the ordinary tribunals. As stated in the Memorandum of the Local Government Board of May 22nd last (R. 198), any such application must be made direct to the Medical Tribunal at 429, Strand, W.C. 2. Each practitioner is notified by the Ministry of National Service when his case comes under consideration by them as to the time within which an application for exemption may be made, and the application cannot be lodged until the notification has been received. A special form of application has been prepared for the use of medical practitioners which may be obtained by them from the Medical Tribunal.

AN Exhibition is being held at the Whitechapel Art Gallery illustrating women's war work. The Exhibition will be open free daily, from Wednesday, Oct. 9th, to Wednesday, Nov. 20th, from noon to 7 P.M.; Saturdays and Sundays, noon to 8 P.M.

ELSIE INGLIS LONDON MEMORIAL FUND.—Recent events in Serbia are rapidly bringing nearer the day when the Chair of Medicine in the University of Belgrade can be inaugurated in memory of Dr. Elsie Inglis's work in Serbia. The Elsie Inglis London Memorial Fund has been founded expressly to endow this Chair. On the General Committee are the names of Miss Aldrich-Blake, M.D., Dr. M. Curcin, Sir Walter Fletcher, and Sir Alfred Keogh. Of the £12,000 required over £2500 have already been promised or subscribed. Donations may be sent to the Elsie Inglis London Memorial Fund at 66, Victoria-street, London, S.W.1.

"Audi alteram partem."

MEDICAL MEN IN PARLIAMENT: MEDICAL RECONSTRUCTION.

To the Editor of THE LANCET.

SIR,—There are two important points to which I should like to call attention.

Medical Men in Parliament.

(1) I am afraid that I did not make my meaning clear at the meeting at Steinway Hall on Oct. 1st,[1] and as the matter is a very important one I shall be glad if you will allow me to explain it further. The chief point which I wished to emphasise was that, whether the medical representatives in Parliament were many or few, it was most important that the profession should keep them thoroughly informed of the views of practitioners following different lines of practice and practising under different circumstances (e.g., country or town), and of the reasons for those views. In this way their representatives in Parliament would have before them the various sides of the problems, and would therefore be able to decide with some degree of certainty and unanimity, after consideration of the various points, what is the most suitable line to take when these matters come before Parliament, and what lines will most closely represent the considered experience of the various classes of practitioners.

During the year that I have been in Parliament I have only twice had views brought before me in connexion with medical subjects which were under discussion. This is not the way in which other professions or trades manage their business; there is no important subject, with the single exception of medicine, which has come before Parliament in my short experience with regard to which we have not received many reasoned letters and leaflets from the parties concerned. To keep the medical Members in Parliament fully informed as to facts and views is really as important a matter as, and possibly more important than, that of the actual number of members of the medical profession in Parliament. I hope, therefore, that during this reconstructive period men in different branches of the profession and practising in various parts of the country will come together and place their views and experience before the medical Members in Parliament in connexion with any medical subject which is under discussion.

Medical Reconstruction.

(2) The time is approaching when civilian medical men who have been serving for a long time abroad will be coming back, and it behoves those of us who have remained in England to do our best to help them out of the difficulties in which their long absence from their practices may have placed them. This matter was, I believe, discussed some considerable time ago by the British Medical Association but was dropped for a time. I think, however, that it must be taken up again without further delay. The needs of these men will be various. Some who have partners who have been keeping things together may be able to resume their practices without requiring any help and the same applies to those who have some private means. There are many others, however, who, if they are not helped to re-establish themselves, will be in very serious trouble. Such are:—

(*A*) Men without partners who have been absent for a long time and who may find that, in spite of the best services of their neighbours, their practice has more or less disappeared, at any rate for a time; but still if they can settle down again in the same place a good deal of it may return and a fresh practice may be established. But I fear that a good many of the men of this class will find it difficult to wait long enough and may require some temporary financial assistance to enable them to regain their position.

(*B*) A good many will have lost their practice altogether and will have to start afresh. Two things may be required for such men: in the first place information as to suitable places to settle in—e.g., where doctors are most needed, and in the second place temporary financial assistance.

(*C*) Men who have not previously been in practice will require advice and guidance on the same lines as *B*, but I hardly think that they have the same lien on the medical profession for financial assistance as men who have been taken away from their practices. (Incidentally it may no doubt be said with truth that it is the State who ought to help financially to reinstate the medical men whom they have taken away, but the time for action would probably have passed before any tangible result could be got in that direction.)

As to the body or bodies who might undertake this work, it seems to me that, as all the information as regards practices is already in the hands of the various war selection committees or can be most readily obtained by them, they would be the natural bodies to take up the matter of medical reconstruction. There would be no charity in what I am suggesting; no doubt, funds for expenses would need to be collected, but beyond that all that would be required would be a large guarantee fund for the loans. This fund would probably never be called on or only to a small extent, as I believe that those who received loans would look on it as their first duty to pay interest punctually and to repay the loans by instalments as soon as possible. If this suggestion is taken up, I for one, and I am sure many others, would be glad to join in forming a guarantee fund and in subscribing towards the expenses.

I am, Sir, yours faithfully,

Oct. 7th, 1918. W. WATSON CHEYNE.

[1] See report in THE LANCET of Oct. 5th (p. 465).

MEDICAL MEN IN PARLIAMENT.

To the Editor of THE LANCET.

SIR,—In accordance with the voting of those who attended the meeting of the profession at Steinway Hall on Oct. 1st, the following have been invited to serve on the committee appointed for the purpose of "taking such steps as may be possible to further the election of medical men to the House of Commons." Representatives of the Royal College of Physicians, Royal College of Surgeons, Royal Society of Medicine, Medical Department of the Royal Navy, Royal Army Medical Corps, Royal Institute of Public Health, British Dental Association, British Medical Association, Incorporated Society of Medical Officers of Health, Medical Society of London, Medico-Political Union, Medical Women's Federation, National Medical Union, Poor-law Medical Officers' Association, State Medical Service Association, the Editor of *The Lancet*, the Editor of the *British Medical Journal*, the Editor of the *Medical World*, Mr. Ernest Clarke, Dr. W. F. H. Coke (Ashford), Dr. R. A. Gibbons, Dr. Wm. Hodgson (Crewe), Sir Thomas Horder, Mr. Lockhart-Mummery, Dr. Arthur Latham, Dr. R. R. W. Logan (Ashby-de-la-Zouch), Dr. J. C. Lyth (York), Dr. H. Moreland McCrae, Dr. J. A. MacDonald (Taunton), Dr. Howard Marshall (Cirencester), Sir Henry Morris, Bt., Dr. E. H. M. Stancomb (Southampton), Dr. Barbara Tchaykovsky, Mr. E. B. Turner, Dr. Jane Walker, Colonel A. S. Woodwark, C.M.G.—I am, Sir, yours faithfully,

Portland-place, W., Oct. 8th, 1918. ARTHUR LATHAM.

To the Editor of THE LANCET.

SIR,—At the meeting held on Oct. 1st I ventured to suggest that some society, which included those who are interested in the care of the insane, should be among those nominating representatives to the proposed committee. This met with a very unfavourable reception from Sir Henry Morris, the chairman, who did not appear to regard the matter at all seriously. With all due deference to him, I do not think this suggestion should be brushed aside lightly. The consideration of the welfare of the insane has been frequently before Parliament in the past, and judging from the last report of the Board of Control is likely to be shortly before it again. The questions of earlier voluntary treatment for the poor without certification, the prospect of the foundation of psychiatric clinics in association with the universities are matters of vital public importance.

The Medico-Psychological Association has a membership of about 700, numbering among them practically all who are engaged in this branch of medicine, together with many neurologists, school medical officers, and others who are interested, and should, I think, be in close relationship with those representing the profession in Parliament.

I am, Sir, yours faithfully,

M. A. COLLINS, M.D.,
Lieutenant-Colonel, R.A.M.C.

Ewell War Hospital, Epsom, Oct. 7th, 1918.

HYPNOSIS IN HYSTERIA.

To the Editor of THE LANCET.

SIR,—It is pleasing to find that Captain D. E. Core is so closely in agreement with my theoretical views. But from the standpoint of practice there seems to be justification for me to add one or two brief remarks:—

(*a*) In my form of the hypnotic method I dispel the hysterical symptoms, not by suggesting them away, but by producing "abreaction" of the emotional state which was responsible for their production. In other words, I make the patient live again through the original emotional occurrence with hallucinatory vividness. In this way I not only clear up the amnesia which is almost invariably present as a symptom in hysterical cases fresh from the firing line, but I also obtain for the patient a strong re-synthetising factor in the liberated emotion. In *every one* of the 121 cases of hysterical mutism that passed through my hands in France, this method restored the power of speech within a few minutes. Other symptoms were cleared up in the same way.

(*b*) I find as a result of practical experience of hysterical cases that the concepts "dissociation" and "repression of emotional states" are of more help in explaining both hypnosis and hysteria than the vague concept of "suggestibility." In fact, they are needed by anyone who wishes to understand the manifestations of suggestibility in concrete instances.

(*c*) Captain Core says that the rational method of cure is "the resolution of the symptoms through the patient's own consciousness." With this I entirely agree. But I find from experience that in a certain proportion of acute cases, where amnesia is present, it is essential to bring the repressed emotional experience back from the unconscious into clear consciousness if the rational method of persuasion is to produce a permanent cure. And my method of hypnosis is both an expeditious and a safe way of doing this.

(*d*) In many cases of hysteria, and in all cases of neurasthenia, the method of hypnosis can be entirely dispensed with. Close inquiry into the patient's past history, the recall of dim memories by the method of free association, and the careful explaining to the patient as to how his symptoms have originated, together with the arousal of sthenic emotions, such as an enthusiastic expectation of cure, will suffice in these cases. To sum up the whole method I have suggested the term "autognosis," since it is a thoroughgoing theoretical and practical knowledge of self which makes a psychoneurosis or a psychosis impossible.

I am, Sir, yours faithfully,

WILLIAM BROWN,
Major, R.A.M.C.

Craiglockhart War Hospital, Edinburgh, Oct. 5th, 1918.

THE PROPHYLAXIS OF VENEREAL DISEASES.

To the Editor of THE LANCET.

SIR,—Such a stirring letter as that which appeared in your columns of Oct. 5th over the signature of "M.D., F.R.C.P., F.R.S." is worthy of the hearty and prompt support of all members of the medical profession who recognise the truth urged by your correspondent that medical prophylaxis is the most potent weapon against the spread of venereal diseases. It is to be hoped that the medical profession, as well as the general public, will assist in promoting in every possible way the proposed active propaganda for staying that plague which is still infecting, disabling, and ultimately destroying more men and women in this country than at any previous time.

Much has been done, though very recently, towards compassing the definite object of preventing venereal infection rather than relying on early treatment of the contracted or suspected disease; but it is none the less true that every move in this direction has been strenuously opposed either by public denouncements or by far more effective influences brought to bear on it by other ways and means. True though it is that many medical men have spoken out very clearly on this subject, and not without a large measure of successful effect, it is equally true, as your correspondent says, that no active steps have been taken by the medical profession as a body to urge the necessity of the earliest possible preventive disinfection in the case of venereal as in all other kinds of infectious diseases. This omission to act is largely due to the fact that many of those who are best instructed and feel most strongly regarding the extent and urgency of this evil have been, and are, greatly hampered by the positions held by them in the Army and Civil Service, and, though to a less extent, in the Navy. It is within my own knowledge true that numerous officers in all these services are prevented from acting and speaking out by official restrictions alone. Nor can it be doubted that, such restrictions apart, the influence of the great body of our medical officers of health, whose leading function it is to bring medical science to bear on the prevention of infection, would have made itself powerfully felt throughout the community.

Rather than to cast any blame whatever on those who have been thus prevented from taking combined action, the occasion now once more presents itself for the medical profession, and with their guidance for the public generally, to exert themselves to the utmost in insisting that the present scientific knowledge of the prevention of venereal infection should be duly and promptly utilised in practice. Though much has been accomplished, much more effort is needed before a sufficiently great and effectual barrier can be put up against the instant mass of disease now oppressing this country, and spreading thence into other lands. Both nationally and politically the seizure of the occasion is of high practical importance.

I am, Sir, yours faithfully,

London, Oct. 6th, 1918. H. BRYAN DONKIN.

PS.—Please allow me to say that I have no knowledge of the identity of your correspondent.

NOTIFICATION OF INDIGENOUS MALARIA.

To the Editor of THE LANCET.

SIR,—It has been obvious for some time that, owing to war conditions, cases of indigenous malaria would sooner or later occur in this country. This anticipation has now been realised. To what extent cases have arisen in other districts during the last few weeks I do not know; but last week I had the opportunity of seeing an undoubted case in a member of the civilian population in this neighbourhood. The following history was given by his medical attendant:—

A middle-aged gentleman, of active business habits, he was in excellent health until Sept. 21st, when he began to shiver soon after going to bed. He thought he was beginning an attack of influenza. In a few hours, however, it passed off, and he felt quite well until the third day when the shivering attack recurred. Briefly, he has had recurring typical malarial attacks every alternate day since. Latterly they have become more severe. Each lasts about six hours. They anticipate by a few hours. I saw him on Oct. 2nd, in the late afternoon, when his attack was coming to an end. His appearance was typical, and a blood film showed numerous parasites of benign tertian malarial fever. This patient has not been out of England since the war began. Whether he has ever been abroad in his life or not I cannot say, but he has certainly never lived in a malarial country or suffered from malaria before. He has therefore been infected in England, probably during the month of September, 1918. During that month he has made short visits to one or two large towns in various parts of the country, occasionally staying the night. It is thus uncertain whether he has received his infection there or at home.

My object in writing this letter is not merely to record this, the first indigenous case I have seen in a civilian, but to call the attention of those who control our public health affairs to the importance of making these cases notifiable as soon as possible. With the end of the war thousands of our troops will be returning from the East, many infected with malaria, and the likelihood of indigenous cases arising on a much larger scale is very great. We ought to be obtaining such information as will enable us to advise simple precautions in those areas in which they may be necessary. The first step towards this is compulsory notification.

I am, Sir, yours faithfully,

Sheffield, Oct. 8th, 1918. ARTHUR J. HALL.

CHRONIC INTESTINAL STASIS.

To the Editor of THE LANCET.

SIR,—Much evil has been laid at the door of man's supposed rise from a quadrupedal posture, and perhaps more at the door of chronic intestinal stasis. Now Dr. Leonard Williams, in THE LANCET of Oct. 5th, has declared that the first bogey is the "*causa causans*" of the second. The cause of chronic intestinal stasis, and therefore the origin of

such a multitude of human ills, is said to be found in the fact that man has departed from the "posture and gait of his quadrupedal ancestors." One would like to know what evidence can be furnished by clinicians in support of the thesis that man is descended from quadrupedal ancestors. Slowly, but surely, such a view of man's phylogeny is passing away. In the last issue of *Nature* (Oct. 3rd), Professor Giuffrida-Ruggeri himself admits that "it is evident that Hominidæ never passed through a quadrupedal stage." The clinician must abandon this much-abused solution unless he can provide some evidence in its favour far better than anything hitherto put forward by anthropologists or anatomists.

The second lesson that Dr. Leonard Williams deduces from a study of chronic intestinal stasis will not commend itself to zoologists. He tells us that our "damnable heritage of the colon would be infinitely less damnable if we treated ours" as the quadrupeds treat theirs. And he says that they treat their colons "to long periods of complete rest," and that they go "for several days without food." Some animals do these things from the necessities of their life-habit, and it will be admitted, I think, that those animals which make frequent fasts of necessity are those having the *shortest* and *simplest* colons. When an animal has a large colon it is generally a certain indication that the creature is one that spends most of its waking hours in feeding. Did we set ourselves to follow the examples of quadrupeds having large colons we should continually munch vegetable matter, and agree with Moses as to the limitation of fasts.

I am, Sir, yours faithfully,

F. WOOD-JONES,

Hunter-street, Oct. 5th, 1918. Captain, R.A.M.C.

THE SERVICES.

ROYAL NAVAL MEDICAL SERVICE.

Fleet Surg. J. C. Ferguson placed on Retired List at own request with the rank of Deputy Surgeon-General (Retired).

Placed on Retired List: Surg.-Gen. G. Welch, C.B.

To be Surgeon-General: Deputy Surg.-Gen. G. Wildey.

To be Deputy Surgeon-General: Fleet Surg. E. C. Lomas, C.B., D.S.O.

ARMY MEDICAL SERVICE.

Lieut.-Col. J. F. Martin, C.M.G., R.A.M.C., to be a temporary Deputy Assistant Director-General.

ROYAL ARMY MEDICAL CORPS.

Temp. Hon. Lieut.-Col. Sir J. Bland-Sutton (Major, R.A.M.C., T.F.) relinquishes his temporary honorary commission on re-posting.

Temp. Major J. A. Wait (Lieutenant-Colonel, R.G.A., T.F.) to be emporary Lieutenant-Colonel.

Major H. F. Shea relinquishes the acting rank of Lieutenant-Colonel on re-posting.

Capt. H. C. D. Rankin to be acting Lieutenant-Colonel whilst in command of a Medical Unit.

Capt. M. P. Leahy relinquishes the acting rank of Lieutenant-Colonel.

Lieut. (temp. Capt.) G. H. Haines to be Captain.

H. W. Doll, late temporary Captain, is granted the honorary rank of Captain.

Temporary Lieutenants to be temporary Captains: C. P. Strong, A. Mills, E. Macmillan, A. Lowndes, I. H. Lipetz, W. P. Lowe, C. H. Ripman, E. L. Holland, T. Drysdale. J. F. Allan, A. B. Waller, R. C. W. Spence, F. H. Whyte, J. T. Grierson, W. M. Thomson, C. W. Alford, T. C. Hynd, W. Bain, S. W. Green, W. Loke, G. Price, J. C. Ogilvie, F. C. Mason, J. Findlay, G. A. Crowley, W. P. Bonner, A. J. D. Cameron, R. H. Calvert, J. B. H. Beatty, S. K. Hutton, A. R. Moir, D. H. Trail, H. M. Johnston, T. F. Ryan, F. P. B. MacTavish, J. G. Lessey, J. Macnamara, J. Magner, W. Murphy, P. D. Maclean, R. W. H. Meredith, W. H. C. Patrick, H. E. Alexander, A. H. L. Thomas, S. M. Green, D. Wardrop. J. B. C. Brockwell, A. B. Fearnley, T. J. D. Quigley, G. R. Harcourt, S. E. Cathcart, T. A. Clarke, H. H. James, I. C. MacKenzie, C. Murray, S. Vosper, H. F. Powell.

G. A. Borthwick, late temporary Captain, is granted the honorary rank of Lieutenant.

Officers relinquishing their commissions: Temp. Majors C. B. Heald, F. F. Muecke; Temp. Capts. J. McIntyre, L. S. Hooper, H. P. Helsham, E. F. Thomas, J. R. Dick, W. Corbet (on account of ill-health contracted on active service and is granted the honorary rank of Captain), G. Munro (on account of ill-health and is granted the honorary rank of Captain), J. Muckart (on account of ill-health and is granted the honorary rank of Lieutenant); Temp. Lieuts. F. W. Maunsell and A. W. Musson (on account of ill-health and are granted the honorary rank of Lieutenant), J. S. Simpson.

Canadian Army Medical Corps.—Temp. Capt. (acting Major) F. C. Clarke to be temporary Major. Temp. Capt. H. C. Mersereau to be acting Major while specially employed.

SPECIAL RESERVE OF OFFICERS.

Major (Brevet Lieut.-Col.) (acting Lieut.-Col.) W. Butler relinquishes his acting rank on ceasing to be specially employed.

Capt. (acting Major) R. S. Taylor is granted the pay and allowances of his acting rank.

Capt. A. L. Flemming is restored to the establishment.

Capt. A. H. Habgood relinquishes the acting rank of Lieutenant-Colonel and reverts to the acting rank of Major (with pay and allowances of his substantive rank).

TERRITORIAL FORCE.

Major T. H. Ionides and Capt. E. R. Clarke are seconded for duty overseas.

Capt. (temp. Major) A. A. S. Skirving relinquishes his temporary rank and is restored to the establishment.

Capt. A. W. Harrington to be acting Major whilst specially employed and remain seconded.

General List.—Capt. (acting Major) J. Dundas relinquishes his acting rank on vacating the appointment of Deputy Assistant Director of Medical Services. Capt. J. R. Menzies to be acting Major whilst specially employed. Capt. (acting Major) J. A. Bell relinquishes his acting rank on ceasing to be specially employed.

ROYAL AIR FORCE.

Medical Branch.—C. D. H. Corbett (late Captain, R.A.M.C.) is granted a temporary commission as Captain, and to be temporary Lieutenant-Colonel whilst specially employed. Major C. H. S. Taylor to be temporary Lieutenant-Colonel whilst specially employed. The undermentioned are granted temporary commissions as Lieutenants: A. Parker, G. M. Wishart, W. J. Lytle.

Dental Branch.—L. Wigoder is granted a temporary commission as Lieutenant.

URBAN VITAL STATISTICS.

(Week ended Oct. 5th, 1918.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality was 12·6, against 11·7 and 11·4 per 1000 in the two preceding weeks. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 12·7, or 0·6 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 3·0 in Smethwick, 3·5 in Gillingham, and 4·4 in Lincoln, to 21·6 in Tottenham, 23·9 in Portsmouth, and 27·3 in Exeter. The principal epidemic diseases caused 278 deaths, which corresponded to an annual rate of 0·9 per 1000, and included 186 from infantile diarrhœa, 36 from diphtheria, 22 from whooping-cough, 13 each from measles and scarlet fever, and 8 from enteric fever. The deaths from diarrhœa, which had declined from 435 to 220 in the five preceding weeks, further fell to 186, and were 92 below the number registered in the corresponding week of last year; 55 deaths belonged to London, 14 to Liverpool, 7 to Birmingham, and 6 each to West Ham, Middlesbrough, and Newcastle-on-Tyne. The 1019 cases of scarlet fever and 1125 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 80 and 65 above the respective numbers remaining at the end of the previous week. Of the total deaths in the 96 towns 103 resulted from violence. The causes of 36 deaths were uncertified, and included 7 in London, 5 in Birmingham, and 4 each in Liverpool and Manchester.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,500,000 persons, the annual rate of mortality, which had increased from 10·6 to 14·3 in the three preceding weeks, further rose to 19·0 per 1000. The 559 deaths in Glasgow corresponded to an annual rate of 26·2 per 1000, and included 12 from infantile diarrhœa, 5 each from whooping-cough and diphtheria, and 1 from scarlet fever. The 88 deaths in Edinburgh were equal to a rate of 13·8 per 1000, and included a fatal case each of whooping-cough, diphtheria, and infantile diarrhœa.

Irish Towns.—The 163 deaths in Dublin corresponded to an annual rate of 21·3, or 1·3 per 1000 above that recorded in the previous week, and included 11 from infantile diarrhœa, 3 from enteric fever, 2 from diphtheria, and 1 each from scarlet fever and whooping-cough. The 72 deaths in Belfast were equal to a rate of 9·6 per 1000, and included 5 from infantile diarrhœa.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Second Professional Examination in Anatomy and Physiology, held on Sept. 26th, 27th, and 30th, and Oct. 1st, for which 70 candidates presented themselves, 42 were approved, and 28 were rejected. The following are the names and medical schools of the successful candidates:—

Douglas Robert Ainsworth, Manchester Univ.; George Kilpatrick Arthur, St. Bart.'s Hosp.; William Beaumont, London Hosp.; Frans Bekker, Guy's Hosp.; John Ryther Steer Bowker, Sydney Univ. and Middlesex Hosp.; Georgie Geddes Brown, Aberdeen Univ.; Hitchon Seater Chadwick, Manchester Univ.; Agnes Eloise Murray Curlewis, Lond. Sch. of Med. for Women; Bernard John Devine and John Roy Dow, King's Coll.; Abdallah Jacob Dowek, Manchester Univ.; Thomas Annesley Eccles, St. Bart.'s Hosp.; Richard Tudor Edwards, London Hosp.; Mathieu Ernotte, Liége and King's Coll.; Ewart William Evans, Birmingham Univ.; Charles Edmund Fenton, London Hosp.; Eric St. Clair Gainer, Middlesex Hosp.; Kate Glyn-Jones, Lond. Sch. of Med. for Women; Leslie Walton Hamp, Birmingham Univ.; Basil John Hancock, Middlesex Hosp.; Sidney Estridge Harvey, St. Thomas's Hosp.; Edward Richard Hughes, London Hosp.; Janet Hughes, King's Coll.; Francis Joselin Jauch, Middlesex Hosp.; David Ellis Jones, Cardiff Univ.; James Trevelyan Jones, Guy's Hosp.; Edmund Oliver Lewis, Cambridge Univ.; Reginald Cyril Lightwood, King's Coll.; Charles Arthur Lindup, Univ. Coll.; John Nigel Loring, St. Thomas's Hosp.; Frances Mary Margerison, King's Coll.; John Kenneth Milward and Hubert Stanley Morris, Guy's Hosp.; Thomas Dallas Overend, Oxford Univ. and Univ. Coll.; Eric Finch Peck, Liverpool Univ.; Cyril Seymour Coode Prance, St. Bart.'s Hosp.; John Jenkin Rowlands, London Hosp.; Sobhi Riskallah Simaika, St. Bart.'s Hosp.; Margaret Charlotte Scrace, Lond. Sch. of Med. for Women; Maxwell Hamilton Summers, Middlesex Hosp.; John Phillip Traylen, London Hosp.; and Charles Paul Wilson, Middlesex Hosp.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At the First Professional Examination for the Licence in Dental Surgery, held on Oct. 4th and 5th, the following candidates were approved in the subjects indicated:—

Mechanical Dentistry.—C. G. Atkinson, Guy's Hosp.; Fanny Henrietta Bachrach and E. Drayton, Royal Dental Hosp.; E. C. George and Eveline Mary Russell, National Dental Hosp.; and Winifred Hope Thomas, A. K. Wiggins, and Catherine Mabel Williams, Royal Dental Hosp.

Dental Metallurgy.—R. D. Amm, Guy's Hosp.; C. A. Moody, Pennsylvania Univ. and Guy's Hosp

Mechanical Dentistry and Dental Metallurgy.—C. P. Mist, Royal Dental Hosp.; and H. A. Spouse, Guy's Hosp.

Museum demonstrations will be given in the theatre of the College in Lincoln's Inn-fields by Professor Arthur Keith, Conservator of the Museum, at 5 P.M., on Fridays, Oct. 18th and 25th, and Nov. 1st. The demonstrations are open to medical students and practitioners, as well as to first-aid and ambulance students.

UNIVERSITY OF GLASGOW.—The following degrees were conferred on Oct. 7th:—

Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.).—William James Simon Cameron, Alexander Conner Connell, James Smith McLean Gray, Janet Whyte Hepburn, Humphrey Josh Hollis, James Patrick Kilty, Elizabeth Cochrane Loudon (with commendation), Patrick McDiarmid, Mary Jessie Macdonald, Maud Elizabeth Drysdale Mackinnon, Allan Watt McRorie, Margaret Gardner McVey, John Nicol (with honours), Isaac Ladipo Oluwole, Vida Johnston Perry, Marjory Mary Scanlan, Ralph Paterson Smith (with commendation), Archibald Sutherland Strachan (with commendation), James Churchill Vaughan, Hugh Wands, and William Young.

The Brunton Memorial Prize of £10, awarded to the most distinguished graduate in medicine of the year, is on this occasion divided between John Nicol and John G. Harrower (the last-named graduated in July).

A MEETING of the National Baby Week Council will take place at the Armitage Hall, 224, Great Portland-street, London, W. (by kind permission of the National Institute for the Blind), on Tuesday next, Oct. 15th, at 2.30 P.M.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—The opening meeting of the thirty-seventh session of this society was held at the West London Hospital on Oct. 4th. The retiring President, Dr. A. J. Rice-Oxley, inducted his successor, Lieutenant-Colonel E. M. Wilson, R.A.M.C. The new President presented to Dr. Rice-Oxley the Keetley Memorial Medal, and expressed the appreciation of the society for his work during the past session. Colonel Wilson then delivered the presidential address on Ancient Physic. Beginning with trephining in the Stone Age, "to allow the escape of the evil spirit," he traced the development of medical art through the Chaldean and Egyptian epochs. Owing to the prohibition of the study of anatomy at this era clinical knowledge made far more advances than surgical methods, and a number of badly set fractures have been unearthed. Whether Egyptian surgeons removed cataracts is doubtful, although they seem to have operated for pterygium and pannus and frequently to have prescribed eye lotions and salves. The rudiments of public health are discoverable in the Mosaic Law, the connexion between mice and plague being suggested. Chinese and Indian medicine were then reviewed, Colonel Wilson mentioning the claim of the Hindus that Hippocrates derived his knowledge from India. The change from superstition to rationalism was initiated into Greek medicine by Pythagoras, who was the first to pay domiciliary visits.

THE CHADWICK LECTURES.—The first of three lectures by Dr. F. G. Crookshank, entitled the "Story of a New Disease," was given on Thursday, Oct. 10th, at the rooms of the Medical Society of London. Dr. W. H. Hamer, medical officer of health for the City of London, presided. The lecturer, after a tribute to the work and teachings of Sir Edwin Chadwick, gave a sketch of the present conception of the Heine-Medin disease, referring to the recent world-cycle of epidemics that commenced in New York in 1916, and passed to Australia, New Zealand, and Eastern Europe in 1917, reaching England and France in 1918. He then traced the synthetical process by which, since the days of Underwood (1784) and the youth of Sir Walter Scott (1773), our present views regarding epidemiology have been reached, and laid stress on the now-recognised association between many forms of encephalitis and poliomyelitis, &c., and the catarrhal epidemics. He adduced evidence to show that the affection has been present in Europe for centuries in association with similar epidemics and pandemics, and suggested that a key to its understanding might be found in Willis's notion (1661) of an "Epidemical Feavour Chiefly Infestous to the Brain and Nervous Stock." The second lecture will be given on Thursday, Oct. 17th, at 5 P.M., as announced in the Medical Diary.

UNIVERSITY OF BIRMINGHAM.—The Ingleby Lectures for 1918 will be delivered on Thursdays, Oct. 17th and 24th, at 4 o'clock, in the Anatomical Lecture Theatre, by Dr. Peter Thompson, Professor of Anatomy in the University, who has taken as his subject, "Some Problems in Embryology."

CENTRAL MIDWIVES BOARD FOR IRELAND.—The first meeting of the Board was held at the office of the Local Government Board for Ireland on Oct. 1st. The following members were present: Sir W. J. Smyly, Sir J. W. Byers, Dr. E. Coey Bigger, Professor H. Corby, Dr. H. T. Warnock, Mrs. M. Blunden, Miss Annie Michie, Miss J. H. Kelly, and Miss Genevieve O'Carroll. Dr. E. Coey Bigger was elected chairman, Sir A. J. Horne deputy chairman, and Mr. J. E. Devlin was nominated as secretary. The Board appointed a finance committee, and also a committee to draw up rules and regulations to be submitted to the next meeting.

Vacancies.

For further information refer to the advertisement columns.

Barrow-in-Furness, North Lonsdale Hospital.—Second H.S. £250.
Birmingham General Dispensary.—Res. M.O. £360.
Birmingham, Erdington Infirmary, House and Children's Homes.—First Asst. M.O. £325. Also Female Second Asst. M.O. £300
Bristol Royal Infirmary.—H.P. and H.S. £120.
Burton-on-Trent Infirmary.—H.S. £200.
Cambridge Borough Education Committee.—Asst. Sch. M.O. £400.
Central London Ophthalmic Hospital, Judd street, W.C.—H.S. £50.
Dorset County Council Education Committee.—School Dentist. £300.
Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £120.
Dumfries and Galloway Royal Infirmary.—Asst. H.S.
Great Northern Central Hospital, Holloway-road, N.—H.S. £150.
Grimsby and District Hospital.—Res. H.S. £200.
Guy's Hospital, S.E.—Chief Clin. Asst. 1 guinea per attendance.
Huddersfield County Borough.—Female Asst. M.O.H. £400.
Jarrow Borough.—Female Sch. Med. Inspector. £350.
Leamington Spa, Warneford, Leamington, and South Warwickshire General Hospital.—Second Res. M.O. £200.
Leicester, Leicestershire County Council Education Committee.—School Dentist. £400.
Manchester, Ancoats Hospital.—H.P. £200.
Manchester Education Committee.—Two Temp. Asst. Sch. M.O. £400.
Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—H.S. £150
Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Surgeon. £200.
Middlesex Education Committee.—Temp. Asst. Sch. M.O. £400.
National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Res. M.O. Also Jun. H.P.
Northampton General Hospital.—Jun. H.S. £150.
Norwich, Norfolk and Norwich Hospital.—H.P., H.S., and Res. M.O. £400 each.
Nottingham General Hospital.—Female Cas. H.S. £250.
Paisley, Royal Alexandra Infirmary.—Res. Phys
Roll of Honour Hospital for Children, 688, Harrow-road, W.—Female Asst. Phys.
Sheffield Royal Infirmary.—Res. S.O. £200.
Southport General Infirmary.—Hon. Oph. Surg.
Swansea Hospital.—H.S. £250.
Winchester, Hampshire County Council.—Temp. Asst. M.O.H. £400.

Births, Marriages, and Deaths.

BIRTHS.

LAWRENCE.—On Oct. 1st, at Kenley, Gravesend, the wife of Stephen M. Lawrence, M.D., B.S., of a daughter.

LINDSAY.—On Oct. 4th, at 8, Oxford-road, Southport, to Colonel C. H. Lindsay, C.M.G., D.S.O., A.M.S., and Mrs. Lindsay—a son.

MAITLAND SCOTT.—On Oct. 7th, at "Shiplake," Bournemouth, the wife of Temporary Major Maitland Scott, R.A.M.C., of a son.

PRICE.—On Oct. 8th, to Dr. and Mrs. Clifford Price, Children's Infirmary, Cleveland-street, W. 1—a daughter.

MARRIAGES.

BELLINGHAM-SMITH—KENNY.—On Sept. 23rd, at St. James, Spanish-place, W., Eric Bellingham-Smith, M.D., M.R.C.P.Lond., temporary Major, R.A.M.C., to Barbara Mary, daughter of William Charles Kenny, of Freemantle House, Southampton.

MCENTIRE—PHILLIPPS.—On Oct. 2nd, at St. Martin-in-the-Fields, Trafalgar-square, Captain S. D. G. McEntire, R.A.M.C. (S.R.), to Mary Constance, only daughter of the late Major Robert Phillipps and of Mrs. Phillipps.

DEATHS.

BINCKES.—On Sept. 23th, at Woodville House, Gravesend, Frederick William Binckes, M.R.C.S., L.R.C.P., late house surgeon, Gravesend Hospital.

BREEN.—On Sept. 18th, killed in action, Major J. F. Pennefather Breen, R.A.M.C.

KEITH.—On Oct. 2nd, at Kinnermit, Turriff, Aberdeenshire, Robert Donald Keith, M.A., M.D. Aberd., late Principal of the King Edward VII. Medical School, Singapore, aged 41.

WALMESLEY.—On Sept. 23rd, at Malta, of influenza, John Joseph Walmesley, R.A.M.C., aged 42.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

CASES OF SOLANINE POISONING.

A CORONER'S inquiry has just been concluded at Worthing into the cause of the death of two little girls (sisters), aged 8 and 4, who died suddenly on August 11th, under somewhat unusual circumstances. The children suffered a few hours before death from sickness, headache, and diarrhœa, with high temperature. Being unable to trace any evidence of irritant poisoning three medical men were not prepared to express an opinion as to the cause of death. The contents of the stomachs were therefore submitted to Mr. Otto Hehner for analysis, who found in the case of the elder child a very minute trace—about 1/13th of a gr.—of a vegetable glucoside in a crystallised condition. He came to the conclusion that it was solanine and an alkaloid produced from it, solanidine. The contents of the other child's stomach furnished all the reactions which were yielded by the alkaloid solanidine. Almost all the plants belonging to the nightshade family contain the alkaloidal glucoside solanine, which in the body underwent decomposition into glucose and the alkaloid solanidine. Berries of "deadly nightshade," shoots of sprouting or shrivelled potatoes, Mr. Hehner said, contained as much as 7 per cent. of alkaloidal glucoside. That and the alkaloid had marked poisonous properties, and produced vomiting, diarrhœa, headache, lassitude, enfeebled pulse, and heavy breathing. Many cases of fatal results were on record. The symptoms recorded by the medical men agreed in every respect with those observed in cases of solanine poisoning. Mr. Hehner came to the conclusion that both children died from the effects of eating a poisonous substance containing solanine. They might have eaten berries of the woody nightshade, which were very plentiful in the hedges at the time; and it was an equal possibility that at dinner the children ate potatoes which might have been in a decomposed or sprouting condition. Neither solanine nor solanidine was a commercial article, and neither could be obtained by purchase by an ordinary member of the public. It was therefore certain, Mr. Hehner said, that the death of the children was quite accidental. A verdict of "Death from misadventure" was returned.

JOHN OF BURGUNDY.

SUPPLEMENTING the note on a Mediæval Medical Author in THE LANCET of Sept. 21st (p. 410), a correspondent writes: "John was probably an Englishman and was not improbably the same as Sir John Mandeville. I do not think that there were any MSS. of his treatise on the plague (i.e., the Black Death) in French. Nearly all the MSS. of this work are in English libraries (British Museum, Bodleian) and are written in English or Latin. The hypothetical connexion between John of Burgundy and Mandeville was the subject of a very interesting paper by Nicholson, the late Bodleian librarian."

EUTHANASIA.

THE August issue of *Scientia*, an international review of synthetic science published monthly at Bologna (London: Williams and Norgate), contains an article in French by Professor J. A. Lindsay, of Belfast, on the Moral Dangers of Euthanasia. He opens with the question:

En cas de maladie incurable et douloureuse, lorsque le malade demande à être délivré de l'existence et que ses amis y consentent, y a-t-il quelque bonne raison pour que le médecin ne fasse pas usage des moyens certains qu'il possède de hâter une issue inévitable, de mettre fin à des souffrances inutiles?

And after considering the answers given by the ancient Greeks and civilisations of different grades concludes that the modern reply must be:

Il semble donc que, même sans invoquer les sanctions de la religion, en se plaçant seulement au point de vue des intérêts supérieurs de la race, on doive faire une objection des plus sérieuses à l'euthanasie—et *a fortiori* au suicide et à toute forme d'infanticide; qu'elle implique des dangers moraux graves et subtils; que son adoption introduirait un élément sinistre dans la vie humaine et tendrait à l'appauvrissement moral de l'humanité.

FATAL ENTERITIS IN RABBITS.

RABBIT meat is now an important article of diet and had until recently the additional attraction of being unrationed. The fatal disease which is now carrying off young rabbits in great numbers has been shown by Dr. R. T. Leiper, who writes to the *Times* on the subject, to be due to a protozoal parasite, *Eimeria stiedæ*, which invades the gut wall and almost denudes its absorbent surface. Man is susceptible to infection, although but few cases are on record. Rabbit keepers will have to study hygienic principles both on grounds of public health as well as to ensure commercial success.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.1.

Tuesday, Oct. 15th.

GENERAL MEETING OF FELLOWS, at 5 P.M.
Installation of new President: Sir Humphry Rolleston, K.C.B., M.D.
Ballot for Election to the Fellowship. (Names already circulated.)

MEETINGS OF SECTIONS.

Wednesday, Oct. 16th.

HISTORY OF MEDICINE (Hon. Secretaries—Charles Singer, Arnold Chaplin): at 5 P.M.
Presidential Address by Mr. D'Arcy Power.
Paper: Dr. Charles Singer: From Tradition to Observation—a Chapter in the History of Anatomy (with lantern slides).

Thursday, Oct. 17th.

DERMATOLOGY (Hon. Secretary—S. E. Dore): at 5 P.M.
Cases will be shown at 4.30 P.M.
Will Members please note that no Meeting of the Section will be held in December, or in February, April, and July, 1919.

Friday, Oct. 18th.

ELECTRO-THERAPEUTICS (Hon. Secretaries—R. Knox, W. J. Turrell): at 8.30 P.M.
Presidential Address by Mr. C. R. C. Lyster.
Demonstration: Sir James Mackenzie Davidson: Stereoscopic Technique, with practical demonstration.

CLINICAL SURGERY.—These Sections are specially invited to attend this Meeting.

MEDICAL SOCIETY OF LONDON, 11, Chandos-st., Cavendish-sq., W.
MONDAY, Oct. 14th.—8 P.M., General Meeting. 8.30 P.M., Opening Address: Major A. F. Voelcker (incoming President). Demonstration:—Dr. T. B. Hyslop: Degeneration in Art, Music, Science, and Literature.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
FRIDAY, Oct. 18th.—5 P.M., Museum Demonstration:—Prof. A. Keith: Nerve Suture and Nerve Regeneration.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Clinics each week-day at 2 P.M., Wednesday, Friday, and Saturday also at 10 A.M.
(Details of Post-Graduate Course were given in issue of Sept. 27th.)

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.
Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—
WEDNESDAY, Oct. 16th.—4 P.M. Lecture II.:—Dr. C. W. Saleeby: Racial Reconstruction and the Proposed Ministry of Health.

CHADWICK PUBLIC LECTURES, at the Rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.
Lectures on the Story of a New Disease (illustrated by epidiascope):—
THURSDAY, Oct. 17th.—5 P.M., Lecture II:—Dr. F. G. Crookshank: (1) The "Nervous Feavour" of Thomas Willis; (2) Spinal Typhoid; (3) Epidemic Encephalitis.

Communications, Letters, &c., to the Editor have been received from—

A.—Major G. F. Alexander, R.A.M.C.
B.—Capt. T. C. Bost, R.A.M.C.; Surg. E. Bayley, R.N.; Dr. W. A. Bond, Lond.; Prof. W. Bulloch, Lond.; Surg. S. S. Barton, R.N.; Surg.-Gen. R. Blue, Washington; Mrs. M. Breen, Dublin; Major W. Brown, R.A.M.C.; Mr. J. Burns, Edinburgh; Mr. W. Butterly, Liverpool; Capt. G. Bate, R.A.M.C.(T.)

The Treatment OF GUNSHOT WOUNDS OF THE JOINTS.

BY J. CAMPBELL, M.D. LIVERP.,

CAPTAIN, R.A.M.C. (S.R.); LATE SURGICAL REGISTRAR, ROYAL INFIRMARY, LIVERPOOL; SENIOR ASSISTANT TO THE PROFESSOR OF ANATOMY, ROYAL COLLEGE OF SURGEONS IN IRELAND, ETC.

PART II.[1]

TREATMENT OF WOUNDS OF THE INDIVIDUAL JOINTS.

Shoulder-joint.

WOUNDS of this joint are complicated by injury to the lung so frequently that a special examination should be made of the chest; this should never be omitted when there is only an entrance wound.

Early cases are treated merely on the lines already laid down, but when complicated by lung injury some hours should elapse before operation to allow of time for compensation of the heart and lungs to meet the new conditions. After excision of the wound every attempt should be made to close the joint cavity, but in most cases this is anything but easy. Should the head of the bone be severely fractured it is excised, by preference, through the original wound. If the fracture is not severe a partial excision is all that is required. In any case, every effort should be made completely to close the wound—nearly all cases so treated do very well indeed.

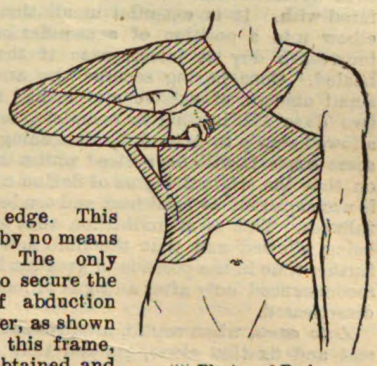
Late cases should be interfered with as little as possible unless a septic arthritis arises; quite a number of these settle down if the limb is efficiently immobilised and extended. In some, however, the infection breaks outside the joint and forms an extra-articular abscess—usually under the deltoid. Such an abscess may be drained behind at the posterior margin of the deltoid, either above or below the line of the circumflex vessels and nerve, according as the treatment necessitates the patient lying down or sitting up. These abscesses, if neglected, may track downwards on to the back under cover of the latissimus dorsi, less commonly forwards under the pectoral muscles, sometimes downwards in the arm, following the line of the brachial vessels and nerves or the musculo-spiral nerve.

Should the head of the bone be at all severely damaged and infection arise, excision is the only course left open. It is best carried out after enlarging the entry or exit, if either of these be of any size; otherwise the anterior route along the pectoro-deltoid groove offers the best advantages, combined with posterior drainage. When excising the joint care should be taken to remove as little bone as possible beyond the anatomical head on the inner side and to leave intact the long head of the biceps. Should it be necessary to interfere with the tuberosities, all available bone should be attached to the tendon insertions and not stripped off them even subperiosteally—otherwise a flail joint is liable to result.

Position of the joint during treatment.—After a wound the joint should always be carefully immobilised and as far as possible extended. In early cases a simple and more or less satisfactory method is to make the patient into a "sitting-case" and sling the arm by a narrow fold round the wrist; the weight of the arm alone secures a certain amount of extension. Fixation is secured by strapping the arm firmly to the chest and finally applying a tight bandage over all. At subsequent dressings the strapping is, of course, left untouched.

In later cases, and many early ones, too, better results are obtained by securing the arm in extension with a Thomas's arm splint at right angles to the side—but generally the ring of the splint is in the way of the wound. This disadvantage may be overcome as follows: the patient is treated lying on the back; the arm is secured by weight extension at right angles to the body and slung meanwhile from a Balkan frame lying crossways of the bed. In such a case dressings would only be infrequently changed (once every three to seven days), and then by sliding the bed to one side from under the patient, so that the back of the shoulder lies exposed over the edge. This method, however, is by no means really satisfactory. The only efficient method is to secure the patient in a sort of abduction frame for the shoulder, as shown in Figs. 2–4. Using this frame, good results can be obtained and dressings readily changed without any disturbance to the joint and consequent reactionary rise in temperature. Later on, when the patient is in a fit condition to get up, the frame is replaced by a suitable plaster jacket and support securing the arm in abduction. (Fig. 5.)

FIG. 5.



//// Plaster-of-Paris.

When extension is applied to the limb one of the great things to be guarded against is a stiff elbow; to avoid this the extension should be applied above the elbow and the joint bent up once every day.

The position for ankylosis varies according to the needs of the patient in after-life. If a freely movable arm is required ankylosis should be secured in abduction at an angle of about 80°, with slight external rotation and slight flexion. On the other hand, if a limb is required possessing more stability than mobility ankylosis should be secured in abduction at an angle of 40° to 45°. Every gradation between these two may be obtained. When ankylosis is secured in the abducted position the arm always readily falls in to the side, merely by the action of gravity and rotation of the scapula on the chest wall. Abduction of the arm from the side later on is secured in the same way by rotation of the scapula from contraction of the serratus magnus muscle.

The practice, so often carried out, of treating cases liable to be followed by ankylosis with the elbow close in to the side cannot be too strongly condemned; an arm ankylosed in this position possesses no range of movement and requires subsequently a cuneiform osteotomy below the seat of ankylosis to secure abduction.

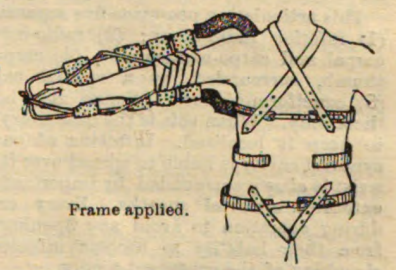
Frame, back view.

FIG. 4.



Frame applied.

Elbow-joint.

This joint is of special interest from the fact that it is comparatively uncommon to have to interfere with it drastically in cases of infection.

[1] Part I. was published in THE LANCET of Oct. 12th, 1918, p. 477.

Rest and fixation are best secured in all cases by fixed extension with the arm supinated in a straight Thomas's arm-splint. But this position must not be maintained for long, as a stiff elbow is so liable to result. An elbow that becomes stiff in extension is most difficult to get into a flexed position. It should be flexed as soon as possible.

Early cases treated efficiently, as previously described (under general treatment) yield most satisfactory results, in spite of the inability to close and isolate the joint cavity in the greater number of cases. This is particularly so after partial excision. Total excision is but rarely required—only for cases of comminution of the ends of all three bones forming the joint. The olecranon process, if anything like intact, is best left untouched; a better functional result is then obtained and the insertion of the triceps least interfered with. It is essential in all these cases to bend the elbow into a position of acute flexion by the twelfth or fourteenth day at latest, even if the wound is not yet healed. Once having secured the arm in this position a small amount of passive movement [2] is used every one or two days till healing is complete, and then the limb is allowed slowly to extend by slackening the sling daily. In some cases it will be noticed whilst this treatment is going on that the original degree of flexion cannot be obtained: it is accompanied by local heat and tenderness and sometimes fullness. This is an indication that too much movement is being allowed and that the limb must be kept at rest for a further time in the position of greatest flexion. Movement is recommenced only after all signs of local inflammation have disappeared.

Late cases, when septic, usually readily settle down with rest and fixation alone, granted that any retained foreign body and loose bone are removed. Sometimes drainage by lateral incisions may be required.

In a small number of cases the constitutional disturbances from toxic absorption are severe; under these circumstances, to allow of freer drainage and relief of tension, a partial subperiosteal excision of the joint should be used. Only the minimal amount of bone should be removed compatible with efficient drainage. It will depend on the injury as to which bone should be removed—naturally preference must be given in most cases to that already damaged; accordingly it would be part of the articular end of the humerus alone, or of the olecranon alone. Should the entire articular surface of the ulna require removal it is advisable to remove the articular part of the radius as well; by this means the risk of ankylosis between the two bones and consequent loss of pronation and supination in the forearm may be avoided.

As soon as the acutely septic stage has subsided, it is essential for the elbow to be slung in acute flexion and the position changed slightly every couple of days to try to avoid ankylosis.

Wrist-joint.

This articulation possesses five separate synovial cavities: (1) inferior radio-ulnar; (2) radio-carpal; (3) the main carpal and carpo-metacarpal; (4) carpo-metacarpal of the thumb, surrounded by a special capsule of its own; (5) cuneiform-pisiform. Sepsis may be limited to one of these only. When this is the case every effort must be made to keep it localised. Infection of one part of the main synovial cavity is liable to spread over its entire extent. The wrist is *closely* surrounded by important tendons enclosed in extensive synovial sheaths. Every care must be taken during operation to avoid any opening of intact sheaths, from their liability to become infected, with consequent sloughing of the contained tendon.

Early cases.—After excision of fleshy parts of the wound, any fractured carpal bones may be excised with gouge and mallet, preferably subperiosteally. The wound is then treated with B.I.P.P. and carefully packed with paraffinised gauze.

Late cases.—Here similar treatment yields the best results, and it is preferable to leave the case undressed for several days at a time to secure good rest and fixation. If the infection is severe and not localised to the site of injury, all the carpus should be removed subperiosteally as far as possible, save the trapezium—this must, if possible, be left intact to allow of movement of the thumb, especially as this carpo-metacarpal joint is separated by a special capsule from the main synovial cavity.

[2] Once only, not repeated to-and-fro movements; otherwise reaction may be obtained.

Rest and fixation.—The best method of mounting in all cases is in a Thomas's arm-splint, the extension bands being attached to dorsal and palmar aspects of the hand. Should this be impossible a Jones's "cock-up" splint, suitably applied to allow of the dressings being made, should be used.

When a Thomas's arm-splint is used it is important, as soon as the sepsis has settled down, to replace it by a "cock-up" splint. Dorsiflexion is most important, as then the grip of the flexor muscles of the hand is excellent. If ankylosis is secured with the wrist straight there is practically no power in the hand.

Hip-joint.

Gunshot wounds involving the hip-joint are amongst those with the highest mortality met with in the war. This terrible fatality is the result of a series of factors: 1. Shock and blood loss are usually marked. 2. It is usually associated with a fracture of either the femur or the pelvis, or both, each of these in itself being a grave matter. 3. There is often severe damage to the gluteal muscles, and these are particularly prone to gas gangrene. 4. The joint is so near the centre of the circulation that septic absorption is rapid and considerable. 5. The head of the femur is so closely gripped by the circumferential ligament, and the capsule so dense and inextensible, that with the onset of septic arthritis tension very rapidly becomes high and toxic absorption correspondingly great. 6. The joint is so deeply placed that the onset of arthritis is not readily indicated by physical signs. 7. Prolonged convalescence, with its exhausting effect on the patient, is required to ensure recovery. 8. Should amputation be required, disarticulation at the hip-joint is associated with a heavy mortality.

Early cases.—Shock and blood loss are such marked features that at first they entirely dominate the case. They must first be recovered from before the serious surgical measures required are resorted to. Resuscitation as usually carried out means at least a delay of several hours. To my mind, it is this delay that is the chief ultimate factor concerned in the high mortality—it allows of the establishment of a virulent sepsis that passes beyond the immediate limits of the wound.

Resuscitation, to be of real value, must be rapid and efficient. The patient must be quickly warmed up and large quantities of fluid (even as much as 4–5 pints) injected intravenously, combined, if need be, with blood transfusion. This should be immediately followed up by operation. As an anæsthetic gas-oxygen is essential to success. Only in this way can even moderately satisfactory results be obtained.

The case is then treated on the same lines as any other early one. If the neck of the femur be fractured to such an extent as to imperil its blood-supply, it is absolutely essential to excise the head of the bone and all loose fragments. Treated in this way at an early stage, quite a number of cases do progress satisfactorily. A number of cases I have treated have done well after having a foreign body removed from the interior of the joint and the bone. I have always found it impossible to suture the capsule.

Should the wound be already septic the widest excision must be practised and the head of the bone removed at once, if the patient will in any way tolerate such a severe procedure. Otherwise a free arthrotomy, including the removal of several V-shaped pieces from the circumferential ligament to allow of drainage, must be used as a temporary measure, and the head of the bone removed a couple of days later.

Late cases.—Amongst a series of cases that reached the base without operation or, having had an operation, without the head of the femur having been removed the mortality was something like 70 per cent. from sepsis, and this in spite of the utmost care in operation and after-treatment. Once the joint is septic to any degree, it is essential to remove the head of the bone. A small number of the slighter cases of septic arthritis do settle down completely if well immobilised and extended.

The onset of arthritis may be diagnosed, when the neck of the bone is intact, by limitation of movement in every direction. Should there be, however, a fracture of the neck the arthritis has to be diagnosed by the general symptoms and by fullness in Scarpa's triangle, accompanied by acute pain and tenderness on pressure over the head of the bone.

Excision of the head of the femur.—In *early cases* the best route, as a rule, is through the original wound, which may have to be enlarged. Sometimes, however, one or other of the *classical* routes must be used. In *later cases* the latter should always be preferred. The most suitable of these are (1) the antero-external, (2) the posterior trans-gluteal. The latter is not a good route, as a rule; it exposes too large a freshly-cut surface to infection.

In septic cases a route possessing many advantages, especially as regards after-treatment, is that which passes on the inner side of the sartorius, the straight head of the rectus femoris being drawn outwards and even partially divided. This allows of good access straight on to the capsule of the joint at the point where it is closest to the surface. If reasonable care be used there is no danger of damaging the femoral artery, but the ascending branch of the external circumflex artery usually requires to be ligated. Posterior drainage is usually not required if the case be treated with Carrel or B.I.P.P. Should it be required, however, it may be obtained by a partial transverse division of the outer part of the gluteus maximus muscle.

In connexion with the use of the Carrel-Dakin method in these cases whilst the patient is on an abduction frame, it is advisable to add a word of caution. If the liquid passes between the patient's back and the splint the most appalling pressure sores may result with amazing rapidity. For this reason I prefer to use it as seldom as possible.

Splinting.—There is only one satisfactory splint for these cases—Jones's abduction frame. Properly applied, after the head of the bone has been removed, it obviates shortening and allows the patient later to walk on an even keel. But the patient is particularly prone to pressure sores on the back unless the skin is carefully attended to. The only way of doing this is to keep the skin hard and perfectly dry. For this purpose a bandage impregnated with French chalk from a dredger is passed from side to side between the patient and the splint, from the shoulder right down to the thighs. This must be regularly done several times in the 24 hours.

Unfortunately, these cases, before reaching a general hospital, have already got an area of cyanotic and atrophic skin over the sacrum from lying for long periods on stretchers, &c., without being able to move owing to their helpless condition and without having had the skin attended to. It is essential, then, to pay particular attention to the skin over the back from the earliest possible moment. The insertion of pads of wool between the patient and the splint must be strictly forbidden; they are the best means of causing further sores. Should a sore develop, the best treatment is to nurse the patient for a time on his face, with a long Liston splint applied to the normal side and weight-extension to the injured limb in partial abduction.

Amputation at the hip-joint is attended by a frightful mortality in these cases. Should it be deemed necessary, the advantages of using an abdominal tourniquet far outweigh any possible disadvantages. There is practically no blood loss. It should never be applied till anæsthesia is well established, otherwise collapse may occur.

Knee-joint.

This joint, above all others, yields most excellent results with efficient treatment, and demonstrates the necessity for carrying out the fundamentals in treatment previously described. Granted these are efficiently carried out, it is quite uncommon to see a bad result. Its large size and proximity to the surface make it readily accessible for observation. The large surface it presents for toxic absorption renders sepsis here so dangerous to life that careful observation is required from the outset.

The risk from bone injury varies with the bone affected. Injuries to the patella, even when severe, usually progress favourably. Those to the femur are considerably more serious. Those to the tibia are most serious of all; indeed, when the damage to the head of this bone is at all severe and the case is not operated on within several hours it is usually best to sacrifice the limb at once. These cases above all are prone to give rise to a severe septic arthritis. This is probably due to several causes:—1. The cancellous tissue of the tibia is soft and very open, and so bruises readily and extensively. 2. The tibia is further removed from the centre of the circulation than the femur, and its blood-supply is partly recurrent. 3. The medullary cavity is nearer the joint, and so more liable to a myelitis than in the case of the femur.

Early cases are best treated on the general principles described. In this joint bony lesions may often be isolated from the general synovial cavity by using the extensive and loose synovial membrane for plastic methods. In severe fractures of the patella the whole bone may be removed and the synovial cavity closed up by dissecting up the subcrural pouch and turning it down and so closing the joint.

Where the bony damage is extensive, and can be eradicated by doing so, excision of the joint may be used. Every effort must be made to close the wound at once, as cases left open do not do satisfactorily. Excision must never be partial but always complete, in order to ensure bony union. It must be remembered that this is a very severe operation; unless the general condition is fairly good it is best to amputate as a primary measure.

Late cases require great care and skill in treatment; injudicious or over-zealous interference may be attended by disastrous results. When moderately septic it is surprising how many cases settle down with rest and fixation alone, accompanied perhaps by aspiration. When severely septic excellent results may be obtained by drainage, combined with the use of the Carrel-Dakin method.

Drainage by lateral or anterior incisions is only of use in that small number of cases in which the sepsis is limited to the anterior part of the joint. The turning up of a U-shaped flap including the patella is of little or no value. When either of these methods is employed the posterior part of the joint cavity forms a well in which pus accumulates. The patient rapidly emaciates, and sooner or later the infection breaks through the capsule, by way of one or other of the posterior synovial prolongations, into the popliteal space. Thence it spreads upwards into the hamstring region along the sciatic nerve or downwards into the calf along the posterior tibial vessels.

The only method of treatment that I have found satisfactory is to drain the joint by anterior and posterior incisions.[3]

The anterior ones are made in a coronal plane, far outwards and backwards from the margin of the patella, so that the knife enters the joint along the line of the synovial reflections; these incisions extend from the upper extremity of the subcrural pouch to the level of the lateral ligaments, but ending short of them.

The posterior incisions are made in the following way. A small pair of Spencer Wells forceps is passed under cover of the lateral ligaments and thrust forcibly backwards into the popliteal space; the point of the forceps then lies against the head of the gastrocnemius and near to the surface; the outer one lies on the inner side of the outer head of the muscle close to the popliteal vessels, the inner on the inner side of the inner head. The forceps have in their course passed through the two posterior synovial prolongations. The points of the forceps are then cut down upon by vertical incisions through the skin. The edges of these are then retracted and the respective margins of the muscle defined, and the heads divided half across. The capsule of the joint is thereby well exposed. This is next divided transversely outwards on either side from the middle line of the limb to avoid damaging the popliteal vessels. In this way a perfectly free and wide track is made leading from the surface to the back of the joint and allowing of free drainage of the posterior parts of the joint with their prolongations.

Covered Carrel tubes are then inserted as follows: anteriorly four from side to side, one at the uppermost extremity of the subcrural pouch, one under the ligamentum patellæ, and two others intermediate in position; laterally, one under cover of each lateral ligament and passing backwards through the posterior synovial pouches into the posterior wounds. These last tubes only carry two or three pairs of perforations. Other covered tubes are carefully laid on the surfaces of all the incisions. As a general rule no dressings need be done till the second day, when the covered tubes are removed under gas anæsthesia and replaced by uncovered ones, passed along the tracks occupied by the tubes that have been removed. The tubes must be carefully inserted so as not to break down the adhesions that have already formed. On the fourth day the anterior tubes are removed altogether and the lateral ones changed, these being retained until the sixth or occasionally the eighth day.

Using this method for severely septic cases it is surprising how many limbs can be safely saved from amputation.

Should an extra-articular abscess develop in the upper part of the calf, the best method for securing drainage is by an incision along the inner or outer margin of the gastrocnemius, exposing the fascial plane between that muscle and the soleus. The incision is continued along this plane till the abscess is freely opened up. Finally, an incision of ½ to ¾ inch is made crossways of the belly of the gastrocnemius.

Care must be taken in all septic cases to avoid the formation of a *genu recurvatum* during treatment; this is very liable to occur from softening of the ligaments, generally due to sepsis. It is a very crippling deformity.

[3] See THE LANCET, 1917, ii., 186, Figs. A and B.

When either one or both of the lateral ligaments is torn, and the case becomes at all severely septic, this method is useless. I consider that it is always advisable to amputate such a case without delay.

Excision cannot be advocated for severely septic cases owing to risk of septicæmia and the liability for fibrous union to occur as the end-result.

Amputation should be reserved in early cases for those with severe comminution of femur or tibia, or both; in late cases for those with severe septic arthritis or arthritis of moderate degres, accompanied by division of one or both lateral ligaments.

In septic cases it should, by preference, be performed above the knee-joint. Disarticulation is dangerous for two reasons: first, because of the liability to secondary hæmorrhage from the main vessels (in a number of cases that came under my care, and in which it had been done, this complication arose in 50 per cent.); and, secondly, because the subcrural pouch usually becomes shut off by fibrinous adhesions and distended by septic exudate, with the result that toxic absorption takes place to such an extent that the patient's life is imperilled. Should, however, an amputation through the joint be used, it is essential to remove the patella and lay open the subcrural pouch along its entire extent. The pouch in such a case should not be excised.

Preference, to my mind, should always be given to a supracondylar amputation. Should the sepsis be already outside the joint a higher amputation must be seriously considered.

The Ankle and Tarsal Joints.

These joints are characterised, like the carpal ones, by being chiefly made up of small bones. These latter are composed of light cancellous tissue that readily bruises extensively. They obtain their blood-supply from a relatively small extent of their surface, the larger being covered by articular cartilage. As a result, when any of these bones are involved in a gunshot wound that becomes septic, they are particularly liable to a septic osteitis over their entire extent. These facts suggest the necessity, where there is a fracture of any severity, for resorting to a subperiosteal resection of the entire bone involved—the os calcis is the only exception to this, and occasionally the astragalus. In septic cases X ray examinations made at intervals readily show the rarefying osteitis present and its progress, and yield precise information as to the bones requiring removal and the degree and extent of new bone formation.

The extent and relations of the synovial cavities have a most extensive bearing on sepsis and its treatment. Roughly speaking, the mid-tarsal joint divides the foot into two parts—posterior and anterior. Injuries to the bones of the posterior part are less serious and more easily recovered from, as joints of less extent are opened up; on the other hand, injuries to the anterior part are appreciably more serious, as infection is liable to spread over the full extent of the ramifications of the calcaneo-cuneiform synovial cavity, and then necessitate amputation.

It follows that efficient eradication of sepsis should be practised at the earliest possible time; and in order to allow of bone regeneration and maintenance of the length and, to some extent, the arch of the foot, *subperiosteal resection* of the damaged bones must be employed. Granted this is carried out, and the patient is under 35 years of age, bone regeneration takes place and a useful foot may be obtained that would otherwise have to be sacrificed. With efficient rest and fixation it is surprising how often sepsis remains localised. Should it spread, however, in the synovial cavity it may be necessary to remove subperiosteally one or more of the neighbouring small bones—cuneiforms or scaphoid. When operating on these tarsal cases care must be taken to respect those ligaments that separate adjacent synovial cavities.

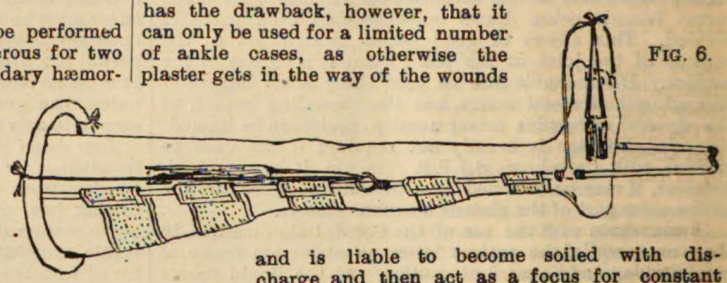
Before resorting to conservative measures it is essential to estimate the amount of concomitant damage to the adjacent tendons: if those of the sole are severely damaged, the foot is best sacrificed at once; but if those of the dorsum only are damaged, it should be remembered that a good deal can be done to remedy the defect at a later date.

The site and extent of any resulting scars, too, are important. Small scars on the outer weight-bearing part of the sole are much more important than those on the inner non-weight-bearing side; indeed, a case that results in a large scar over the weight-bearing surface not infrequently requires amputation later on for pain or recurring ulceration.

Methods of securing rest and fixation.—For the ankle-joint several methods may be used:—

1. *Sinclair's method.*—A Thomas's knee-splint is applied to the limb and extension secured by a plaque of plaster-of-Paris glued to the sole of the foot and secured by bands suitably applied and tied in the ordinary way round the end of the splint. This method is excellent, it allows of absolute rest and fixation with extension. It has the drawback, however, that it can only be used for a limited number of ankle cases, as otherwise the plaster gets in the way of the wounds and is liable to become soiled with discharge and then act as a focus for constant re-infection.

FIG. 6.



2. Probably the most useful method for universal application is that shown in the accompanying figure. (Fig. 6.) The entire limb is secured in a Thomas's knee-splint as follows: Bands of suitable material are glued to the sides of the lower part of the thigh and upper part of the leg and passed through loops of bandage fastened by strapping to the sides of the splint above the ankle, as shown; the bands are then brought up to the ring of the splint, suitably tightened, and fastened off; this secures the limb as a whole in the splint. The limb is supported by metal bands. An arch passing well above the toes is then attached to the sides of the splint and the foot slung from it by material glued to as much as possible of the sole of the foot (the least extent that is essential is only quite small). An effort should always be made to secure the foot in slight dorsiflexion to facilitate walking should ankylosis occur ultimately.

3. Another useful method is to secure the leg in a Jones's malleable iron splint for the ankle, as shown. The splint is first bent in such a way as to allow of free access round the foot and ankle for the application of dressings. It is then applied to the limb and the foot slung from the toe-piece, as described above. (Fig. 7.)

FIG. 7 A.

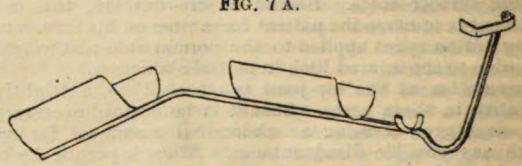


FIG. 7 B.

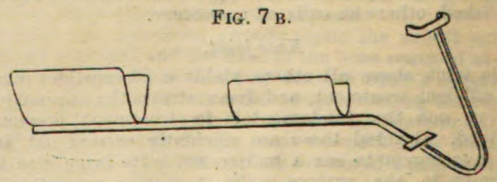

FIG. 7 C.

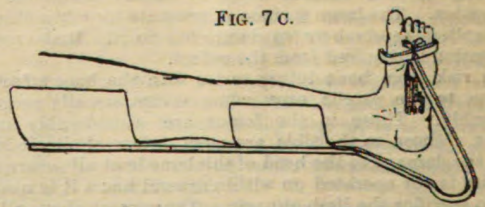

These last two methods are applicable to tarsal cases as well.

The use of a simple back-splint with a foot-piece cannot be too strongly condemned. Rest and fixation are *not* secured, however much care be exercised; movement always occurs with each dressing.

Treatment of Ankle-joint Cases.

Early cases are best treated on the general lines enunciated above and sutured early. Should the astragalus be widely damaged resection is best practised at once, but is a difficult procedure.

Fractures of the tibia and fibula secondarily involving the joint, if not too severe, do well if all loose and contused bone is carefully removed.

Late cases.—With a septic arthritis, when the astragalus is the fractured bone and is more than slightly damaged, it should be resected, arthrotomy being practically useless, save as a temporary measure to allow of some subsidence of the sepsis in the more severe infections. Where, however, either tibia or fibula is the bone involved and the bony damage is not too severe arthrotomy, with removal of all loose bone, often succeeds very well. When the lower end of the tibia is blown away and the joint involved the limb is best amputated at once; such a case is usually accompanied by extensive tendon damage.

Tarsal Joint Cases.

From what has been described above it is readily seen that the treatment of the gunshot wounds of the tarsal joints is inseparable from and dominated by that of the bones involved. For this reason their treatment will be described under the heading of the individual bones.

Os calcis.—Fractures of the os calcis into the neighbouring joints, even when severe, usually do well after removal of all loose and damaged bone. Any extensive resection is to be avoided as far as possible, otherwise the posterior arch of the foot is liable to be lost from collapse of the heel with, in consequence, considerable crippling of the usefulness of the limb.

Cuboid.—This bone, if severely fractured, yields good results after subperiosteal resection as the sepsis is localised to three small synovial cavities. During resection the tendon of the peroneus longus is liable to have its sheath opened and then slough. If this bone alone is removed regeneration is usually complete and the arch of the foot but little affected. Care must always be taken to prevent, as far as possible, any operation scar from extending on to the tread of the foot.

Fractures involving, either severally or collectively, the *three cuneiform, scaphoid and bases of the second and third metatarsal bones* are particularly important from the extent and ramifications of the synovial cavity that is opened up. They require to be treated with more respect than those of the remainder of the tarsus.

Treatment of early cases.—There is no doubt whatever in my own mind of the superiority of the use of B.I.P. paste in these cases over other methods of treatment, chiefly owing to the infrequency with which these cases need then be dressed.

Late cases.—B.I.P.P. here does very well, too, but I prefer to employ the Carrel-Dakin method—the cases appear to do better.

It is essential to success to have X ray plates taken at intervals during treatment so that any further bones requiring resection may be treated early. The plates are useful, too, as giving an idea of the progress of bone regeneration.

Amputation.—Should this be required Syme's operation or some modification of it is undoubtedly the best; should this not be practicable an amputation just below the middle of the leg must be practised. If a Syme's amputation is required for severe sepsis in the neighbourhood it is not infrequently of advantage merely to disarticulate and then leave the fibula and tibia untouched, with the flap fully open. Later on, when the sepsis has subsided, the operation is completed by sawing across the ends of the bones and suturing the flap in place.

CONCLUSION.

Of the operative measures described above I have no hesitation in saying that, efficiently carried out, they yield the best results. Different roads may lead to one town—in just the same way different methods of wound treatment, when used in hands specially trained in their respective employment, may lead to almost equally satisfactory results. Those advocated in this paper are the outcome of an extensive experience in war cases spread over a period of three years' close observation, and built up out of series of successes and, more especially in the earlier days of the campaign, out of not a few failures and disappointments. One thing, at any rate, is certain: no method of wound treatment can ever rectify defective surgical procedures or rectify mistakes arising from failure to follow out the fundamental surgical principles that should have been carried out. It is much more the efficiency of the primary operation than the use or not of antiseptics that is the chief factor in determining successful results.

Finally, I would like to thank Colonel C. H. S. Frankau, D.S.O., A.M.S., consulting surgeon, for the encouragement he has given me in the publication of this paper. In addition, I wish to acknowledge my indebtedness to Sister Miller, R.R.C., for the help she has most willingly given me; a number of the most successful results I have ever had are entirely due to her skilful help and scrupulous technique in the operating theatre.

REPORT ON AN

OUTBREAK OF SCURVY IN THE SOUTH AFRICAN NATIVE LABOUR CORPS.

BY HAMILTON W. DYKE, M.B. GLASG.,
CAPTAIN, R.A.M.C.

THE following report upon an outbreak of scurvy which occurred during the spring of the present year among the South African Native Labour Corps is presented, along with observations as to its causation and suggestions for the future prevention of scurvy in Native Labour Corps.

1. *The S.A.N.L.C.: Conditions of Life and Rations in France.*

The South African Native Labour Corps was brought to France for work on the lines of communication. The natives were recruited from all parts of South Africa, and included Basuto, Bavenda, Xosas, Zulus, and other tribes. They were formed into companies of about 450 men, each with its own interior economy. The conditions of living were, as far as possible, modelled on the system obtaining in the compounds of the South African mines. They were well clothed, well hutted, and the diet speaks for itself—an ample, substantial, and varied diet.

Kaffir Personnel.—Field Ration.

Frozen meat	1 lb.	Fresh vegetables	8 oz.
or Preserved meat ...	9 oz.	Margarine...	1 oz.
*Mealie meal	1 lb.	English tobacco or cigarettes (per week)	2 oz.
Bread	1 lb.	or Kaffir cigarettes (per week)	3 oz.
Coffee	1 oz.	Matches (once a week)...	1 box.
Sugar	2 oz.		
Salt	½ oz.		

* If the full ration is not obtainable, an equal quantity of rice may be issued in lieu.

The conditions of work were excellent, though in some instances, due to exigencies of the services, the hours were long; but as labourers they proved themselves equal to, if not superior to, any labour of its kind in France.

The health of the contingent has, on the whole, been very good. In 1917 I was for six months in medical charge of four companies of the S.A.N.L.C. on one of the country depôts; they were compounded, but given considerable liberty to go out for walks under supervision, and were thus able to obtain a certain amount of fresh fruit from neighbouring apple orchards. There was not a single case of scurvy in those companies during that period. At the end of 1917 I took over medical charge of four other companies of S.A.N.L.C. who had just arrived in France. These men were given work on the docks in one of the port towns. In order to be near the docks they were accommodated in a single large camp, but owing to the congested conditions of the area it was relatively smaller than the camp of the previous four companies, and being in the midst of surrounding docks and suburbs, the liberty of the natives was very much restricted; but as regards cotting, hutting, and diet the conditions were the same as in the previous four companies referred to.

Each company in the camp had its own separate cooking arrangements.

2. *The Outbreak of Scurvy.*

Towards the middle of March, 1918, two natives in "X" Camp (No. 1 Native Labour Camp), of which I had

medical charge, were admitted to the Camp Detention Hospital with symptoms suggestive of scurvy. A systematic inspection was therefore made of the gums of all the natives in the camp; it was found that 40 per cent. showed a tendency to scurvy, the distribution being equally divided in all four companies. Antiscorbutic measures (detailed below) were therefore instituted; these did not interfere in any way with the work of the companies. During the period from March 15th to April 15th 19 cases of definite scurvy were admitted to detention hospital, all four companies being more or less equally affected.

By April 15th, however, gum inspections showed the tendency reduced from 40 per cent. to 10 per cent. Since that date until August only two cases presented themselves, and the periodic gum inspections indicated a tendency to the condition in less than 5 per cent.

In another ("Y") camp (Nos. 4 and 7 Labour Companies) in this area, having the same number as "X" Camp and living under similar conditions, the outbreak was more serious. The diagnosis of scurvy was first made on May 3rd, though I am given to understand that previous to that date a certain number of cases, undiagnosed, had been evacuated to a base hospital. From that date until July 16th 142 cases occurred.[1] With the exception of two, the cases were derived from three of the four companies of the corps. The only difference ascertained in the conditions of the four companies was that the 33rd Company, in which only two cases occurred, was from time to time given prunes and fruit bought by the company commander from company funds. The reason for this large number of cases in "Y" Camp was that the condition had not been recognised when the first cases occurred, and therefore some time elapsed before antiscorbutic measures were instituted. Towards the middle of May these measures were rigidly enforced and by the middle of July the outbreak had practically ceased.

3. *Symptomatology of Cases.*

There was nothing new noted in the clinical aspect of the outbreak. To one who had not seen scurvy before the diagnosis of the early cases might have been missed owing to the absence of gingivitis.

(*a*) The first symptoms with which the natives generally reported sick, and which could easily be ignored, were indefinite *myalgic pains* in the chest, neck, back, and legs, associated with a certain amount of cramp (subjective) in the calf and hamstring muscles. On inquiry they generally admitted to being easily fatigued and breathless on exertion.

(*b*) *Gingivitis.*—This classical sign, though present in most of the cases to a greater or less degree, was in some cases entirely absent. It varied from a slight swelling of the gums and inter-dental processes, with a slight blueness of the gum border, to great hypertrophy of the gum tissue. In a few of the bad cases the gums protruded 1/3 to 1/2 inch. The gums were then very red, ulcerated, and septic, and bled freely on the slightest pressure. Bacteriological examinations of the gums were made by Lieutenant-Colonel C. J. Martin, assistant adviser in pathology, who found the material from the ulcerated edges teeming with spirochætes and *Bacillus fusiformis*. These, which are common denizens of the mouth, had, in Lieutenant-Colonel Martin's opinion, taken advantage of the lowered local resistance to invade the gums. At the weekly gum inspections of the companies one had to rely on the condition of the gums for a measure of the scorbutic taint in the individuals—every native showing slight gingivitis, with bleeding on pressure was considered a potential scorbutic.

(*c*) *Hæmorrhages into muscles.*—This was the most important and prominent feature in almost all the cases admitted to hospital, principally because it lamed the man and incapacitated him for work. In some of the cases it was the only sign present. These hæmorrhages occurred in certain definite muscles or groups of muscles—as a rule the muscles of the calf were affected; next in order of frequency were those of the thigh forming the inner border of the popliteal space. The part affected was swollen to a greater or less degree; pitting on pressure was frequently obtained over an adjoining bone. The swelling was hard and brawny and very tender; it caused the patient considerable pain on movement of the limb. As a rule, only one leg was affected, infrequently both legs, and then the second leg would only be slightly swollen. These swellings occurred at times with great rapidity, which one would expect from a hæmorrhage. A man would sometimes be at work one day, feeling pretty fit; the following morning he would hobble painfully to sick parade with assistance, and one would find the affected calf 2 to 3 inches bigger in circumference than the other. There was no further increase in swelling once the patient was put to bed, and it gradually subsided in five to ten days, but for two or three weeks there remained a certain amount of tender induration.

(*d*) Small *petechial hæmorrhages* into the hair follicles of the leg were almost constant in the cases.

(*e*) Another very constant feature was the roughness of the skin—coarse goose skin—over the upper end of the tibia, and on the legs between knee and ankle.

(*f*) *Anæmia* was present in over half the patients.

(*g*) Cardiac weakness with dilatation was not severe in any of the cases, though in some tachycardia occurred on exertion and a distinct mitral murmur at the apex was present. These disappeared as the patient improved.

(*h*) Subperiosteal and synovial swelling were each seen in one instance.

(*j*) *Fever.* This occurred only in cases where there was much gingivitis, but subsided very rapidly (3 or 4 days) once the oral sepsis was controlled.

The general condition of the patients when admitted to hospital varied; most of them looked ill and drawn, but very rapidly threw this off. In none of the cases did intestinal hæmorrhage occur.

4. *Treatment of the Cases and General Measures Taken.*

The treatment of those already affected consisted of:—

(i.) Full diet with an extra supply of fresh vegetables lightly boiled. When the gums did not allow mastication, solid food was passed through a mincing machine.

(ii.) Lime-juice, ½ oz., was given three times a day. In the last case under my charge I omitted the lime-juice and gave three fresh lemons per diem. The rapidity with which the patient improved was remarkable, notwithstanding the fact that he was well over 40 years of age and had very definite gingivitis and swellings of the legs; none of the previous cases that had been given lime-juice made such rapid progress as this one when the lemons were substituted.

(iii.) Iron in the form of mist. mag. co. c. ferro was exhibited to counteract anæmia and the tendency to constipation.

(iv.) Massage to the affected limb, first very gently but gradually more vigorously when the patient could bear the pressure; ordinary liniment. terebinth. was used as a lubricant.

(v.) The gums were treated three times a day with a mouth-wash of hydrogen peroxide, followed by gentle swabbing with pledgets of cotton-wool soaked in 1 to 60 carbolic solution. As a rule the condition had so much improved in five to seven days that the patients could masticate their food and use a soft tooth-brush.

As soon as the patient was able to hobble about the ward with the aid of a stick he was allowed "up" daily for an increasing number of hours, but he was not discharged until all the induration and tenderness of the affected limb had disappeared, nor until the heart had regained its normal action, tested by exertion. Most of the cases were discharged within five weeks of the onset. After discharge the patient was given light duty for a week, but continued to get his lime-juice and iron mixture. Men of under 40 years made a much more rapid and complete recovery than those over that age. To obviate further trouble the following measures were adopted and enforced, and they proved efficacious:—

1. Acting on instructions, particular attention was paid to cooking of fresh meat and vegetables (see paragraphs dealing with the cause of outbreak below). The time of cooking was not allowed to exceed 45 minutes; the food to be cooked was introduced into water already on the boil, and at the end of from 30 to 40 minutes the fires were drawn, but the food allowed to remain in the boiler until it was required for a meal. When necessary it was heated up again for a few minutes before use.

2. The vegetable ration was supplemented by the purchase of extra fresh vegetables, cabbages, carrots, &c., bought with company funds. The carrots were issued raw, and with a little persuasion the natives ate them willingly.

3. A ration of lime-juice, ½ oz., was issued daily to all natives who showed any tendency to scurvy.

Of these measures, the one that seems to have given the best effect was the reduction in the time of cooking fresh food. This statement is supported by the fact that in —— Company of "Y" Camp, in which the disease was most prevalent, and lasted longest, it was discovered that notwithstanding instructions (though extra vegetable and lime-juice were being issued), the boiling of meat, &c., was being carried on for two hours at least, thus keeping up the disease, which soon improved after the cooking was reduced to 40 minutes.

5. *Cause of the Outbreak.*

(*a*) Summary of knowledge of etiology of scurvy.

Scurvy is usually associated in one's mind with sailors on long voyages in sailing ships, living on salt meat; prisoners undergoing long sentences; expeditions of discovery to Arctic regions; and troops besieged for a long period. Recently it has been a problem with which the medical officer has been confronted in connexion with the employment of coloured labourers, removed from their normal home and surroundings. Scurvy is clearly due to lack of some constituent in a diet which is supplied more particularly by fresh vegetables, and is present in fresh meat to some extent. Scientific research in recent years by Holst, and his colleagues, Frohlich and Furst, of Christiania University, and by the Misses Chick and Hume, of the Lister Institute, have proven that an efficient diet must contain certain active principles which they term "antiscorbutic vitamines," and the lack of which in man and certain animals will produce scurvy. The experiments of Holst, Frohlich, Furst, Chick, and Hume have shown that all fresh fruits, vegetables, and roots contain this principle in varying amount, but that it is sensitive to prolonged drying and heat, so that in desiccated and tinned vegetables, and canned fruits, it is to all intents and purposes absent. The cooking of cabbage for 30 minutes was found by Chick and Hume to reduce its antiscorbutic value to less than half, and prolonged boiling to annul it. Seeds of cereals, pulses, &c., are devoid of antiscorbutic value, but attain it on germination, a discovery the practical importance of which will emerge below.

(*b*) Interpretation of the present outbreak in the light of the above facts.

[1] The number of cases in "Y" Camp are those that have come directly under my observation, and will no doubt vary from those eventually notified at headquarters.

As pointed out at the commencement of this report, these men were upon a liberal scale of rations, according to European Army Scale. Half a pound of fresh vegetables is not, however, any too much for a diet which is partaken of over long periods, and is sailing "near the wind" if no opportunity occurs for supplementing, as takes place in the natural circumstances of the natives. This ration of fresh vegetable probably allowed of no margin for reduction in antiscorbutic value by prolonged heating. On investigation it was found that all food was being cooked by boiling for at least three hours, and except in the case of the 33rd Company no fresh fruit was being obtained by the natives, so that their food was, not unlikely, seriously deficient in antiscorbutic vitamines, due to the destruction of these in the fresh potatoes, onions, &c., by prolonged exposure to boiling.

I attribute the outbreak to a combination of these two causes: (1) Inability in the case of certain companies to supplement the diet occasionally with extra fresh fruit and vegetables; and (2) reduction of the antiscorbutic value of the fresh vegetables supplied by excessive cooking. The marked improvement occurring directly in those companies in which measures were taken to supplement diet and enforce a reasonable period of cooking justifies this opinion.

6. *Suggestions for Prophylaxis in the Future.*

Before considering how to obviate scurvy in future it is well to consider further why natives not infrequently suffer from this disease when confined in camps or mines, &c., whereas there is very little scurvy among them living in their kraals in South Africa. Occasionally in spring one comes across a native who may show a slight tendency to the disease, generally in years when the previous kaffir corn (millet) crop has been a failure, but during the eight years I have been in practice in Basutoland I have never seen a single case of well-defined scurvy occurring among the Basutos living at home. During the summer the native has an abundant supply of fresh vegetables, roots, and fruits, but in his kraal, from April to November (the winter and spring months), the average native obtains no vegetables or fruit. He has meat once or twice a month, but his staple article of diet is a thick porridge made with maize or millet meal, and washed down with large draughts of kaffir beer.

One has frequently wondered why he did not develop scurvy by the end of those winter months. An explanation is, however, to hand in the discovery of Furst, verified and amplified by Chick and Hume, that during the germination of seeds the antiscorbutic substance is developed in large amount, for kaffir beer, of which natives partake largely, up to three gallons a day, is a thin fermented gruel made with a *germinated* millet. Thus in the gratification of his appetite for acid, alcoholic beverages, the native appears, unknowingly, to have protected himself from scurvy during the winter season.

Kaffir beer ("Leting" or "Joala") is made by germinating a small quantity of kaffir corn (millet) by steeping it in water for 48 hours; it is then dried in the sun for a day. The same day or the next it is ground coarsely between two stones. This meal is then placed in a large pot, and to it is added boiling water to make a very thin porridge, to which is added a small quantity of yeast (the residue of a previous brew). Fermentation is thus set up and allowed to continue for 36 to 48 hours, after which the whole is strained through a coarse straw strainer; the resulting opaque brownish fluid constitutes kaffir beer, which makes a very pleasant and satisfying drink. The points to be noted in the making of the drink are that only sufficient grain is germinated and ground for the one brew; never is it done with a view to provision for a future occasion. Again, boiling water is added to the meal, but there is no further boiling. Kaffir beer has been largely used in South Africa to arrest scurvy in prisons and mines. It has also been the practice on the Rand to give natives another acid, fermented beverage, "Mahew," and the natives have been supplied with this since landing in France. This is made from the meal of *ordinary ground maize or millet without previous germination*. The meal is stirred into boiling water and the process of boiling continued for an hour or so until a thin porridge is made; this is then evacuated into vats, and some wheat meal is added to cause fermentation. The porridge, after being diluted with a sufficient amount of hot water, is allowed to stand for 36 hours and is then ready for use. It is much more easily manufactured on a large scale than kaffir beer, and for this reason has been used as a substitute for the latter; but it is now clear why this substitute has been without influence to prevent scurvy.

To sum up, the danger of scurvy amongst South African native troops can be avoided by: (1) Seeing that the value of the limited supply of fresh vegetables is not dissipated by unnecessarily prolonged cooking; (2) supplementing this supply by the purchase of fresh fruit or vegetables from corps funds; (3) provision of mildly alcoholic native beer prepared from *germinated* grain of some sort.

In conclusion, I wish to express my gratitude to Lieutenant-Colonel C. J. Martin, F.R.S., A.A.M.C., for the bacteriology of the gingivitis and for the encouragement and advice he has given me in drawing up this paper.

A CASE OF

ABSENCE OF ALL SENSATION.

BY E. D. ROBERTS, M.R.C.S., L.R.C.P., M.D. LAUSANNE,
CAPTAIN, R.A.M.C. (S.R.).

THE remarkable case described below is that of a Breton sailor, aged 37, who emigrated to Canada eight years ago and enlisted in the Canadian Army in 1916. In June, 1918, he was admitted to the Military Isolation Hospital, Aldershot, for an attack of mumps, and it was then that the following observations were made.

The patient was a well-developed, powerful-looking man, of a very cheerful, even temperament, highly good-natured, and far removed from the neurotic or hysterical type as popularly conceived. Mentally he was perfectly sound, rather above than below the average level of intelligence. Questioned as to his family history, he would appear to be alone in presenting the peculiar characteristics here described. As a child he appears to have possessed a slight degree of cutaneous sensibility, and he dates its complete absence from the time when he had an attack of yellow fever in Senegal at the age of 17. This was his only previous malady, and he has always enjoyed robust health.

It will be convenient to describe the condition found under the heads of the different sensations.

Sense of touch.—There is complete absence of both superficial and deep tactile sense over the whole skin surface, and also over mucous membrane where attainable. There is no consciousness of deep vibration. A tuning fork not being available, a poker, the end of which was allowed to fall from the height of about a foot on to the tibia, the ribs, or the skull, produced no sensation of any kind—the patient, with eyes closed, not even knowing that he was touched. He does not feel the ground with his feet, and experiences difficulty when walking at night. He states that his inability to bring his heels together at the command "Attention" without controlling the movement with his eyes has frequently led him into trouble with his drill-sergeant. There is complete inability to recognise objects placed in the hand when the eyes are shut.

Sense of pain.—This is completely absent. In October, 1916, at the Hôpital de St. Louis at Quebec he underwent the radical cure of double inguinal hernia without anæsthetic of any kind, the patient being totally unconscious of any sensation either of pain or touch. His body is plentifully strewn with the scars of wounds and burns which he has inflicted on himself either for bets or to astonish the onlookers. I have myself seen him on more than one occasion hold a burning match against the skin of his arm for the space of 10 or 15 seconds, and then unconcernedly pick off the charred epidermis. He never suffers from headache, toothache, abdominal or other visceral pain of any description. The cornea, it may be noted, shares in the general anæsthesia.

Thermal sensation.—This is also absent. On placing the fingers in water so hot as to raise a blister, but well below boiling point (the eyes being closed), there was a slight convulsive movement of the hand, and he stated he was conscious of what he described as an electric shock, saying that he remembered feeling such a sensation when a boy. The feeling, he affirmed, was not a painful one. The placing of the hand in cold water evoked no sensation. There is no perception of temperature in food or drink. There is insensibility to atmospheric changes of temperature. The extremes of heat and cold encountered during sea voyages produced no corresponding changes of sensation. He states, however, that the great cold experienced on one occasion while rounding Cape Horn gave rise to vaguely unpleasant sensations. During the attack of yellow fever mentioned above he remembers the fact of his violent shivering followed by profuse sweating, but was unconscious of the feeling of cold or heat.

Muscular sense and sense of position.—The muscular sense appears to be completely absent. With the eyes closed, if asked to make any movement with his arms—the choice of movement being left to him—he is incapable of doing so, saying he cannot tell if his arms are moving or not, and all he can accomplish is a slight convulsive twitching of the hands and arms. On the other hand, if when standing upright with closed eyes he be told to walk

towards the observer he does so without trouble. He states, too, that he is a good swimmer. These two facts are difficult to reconcile with the apparent incapacity to move his arms with closed eyes. Again, if with closed eyes his arms and fingers are extended and any small light object be placed in one hand, and a much heavier object (such as a heavy iron bar or a solidly-made wooden chair) be placed in the other, and he then be told to close his fingers—a movement which he performs with apparent difficulty—he is incapable of saying which hand holds the heavier weight, he is quite ignorant of the nature of the objects, and most frequently he is unconscious of the fact of anything having been placed in his hands. If an object held in the hand be very bulky and if the fingers be closed very forcibly on it he is generally able to say that there is *something* in his hand without knowing what. He appears ignorant of the meaning of fatigue, and asserts that the only means by which he is made aware of his failing strength, under any intense or prolonged effort, is by his falling to the ground.

The sense of position is equally absent. With eyes closed he is unable to bring the tips of the index fingers into contact, to touch the tip of his nose with a finger, or to locate his hand when placed by the observer in any given position. If asked to raise his hand from its position resting on his knee and to touch his head, his eyes being closed, he appears completely nonplussed, and, as noted above, responds only by slight jerkings of the hand. With visual control all his movements are perfectly coördinated and in every way normal.

He exhibits the phenomenon of the fixation of the limbs in the positions in which they are placed. Thus, the patient is placed on his back with arms stretched out by the sides, and legs extended. The eyes are closed. If now the observer takes the patient's limbs and places them in any position (for example, both arms raised in the air above the head, and one leg raised with the thigh flexed and the knee bent), he is totally unaware of having been touched or of any change of position in his limbs, and the arms and legs remain fixed where they have been placed without conscious muscular effort on the part of the patient. On opening his eyes he manifests genuine surprise at his attitude.

Sense of taste.—Completely absent. The patient's eyes being closed, about half a drachm of such substances as sugar, salt, pepper, mustard, also a drop or two of an essential oil (oil of cloves), were in turn placed upon his tongue, and each in turn thoroughly insalivated, and finally swallowed, but all failed to produce any sensation of taste, the patient being unconscious of any substance in the mouth. It may be remarked that he eats anything, as the fancy takes him. On one occasion he was found to have consumed a lump of bath-brick about the size of a hen's egg that a hospital orderly had inadvertently left in his way. He states that he is in the habit of eating uncooked—when he can get hold of them—such animals as rats, mice, dog, or serpent.

It appears that he is never conscious of hunger or thirst. It was not practicable under the circumstances to put this statement to the test, but he relates that for a bet he once refrained from food and drink for eight days and nights. He felt no inconvenience beyond, towards the end of the period, an abnormal tendency to sleep. At the completion of the fast he asserts that he returned to work in no way harmfully affected, and not conscious of any special craving for food or drink. This is recorded without guarantee as to its truth, as it was related by the patient.

Sense of smell.—Practically non-existent. Such characteristic odours as those of the oils of cloves, cinnamon, peppermint, the tincture of orange failed to produce any sensation. Fuming nitric acid was equally ineffective when strongly inhaled. On the other hand, the fumes of the strong solution of ammonia and of pure hydrochloric acid produced a faint sensation of an odour which the patient remembered to have smelt in his youth.

Reflexes.—The only response on both sides to plantar irritation was slight abduction of the little toe. The patellar reflexes were present and normal. The orbicularis palpebrarum muscles contracted on touching the cornea, though no sensation was evoked. The pupils reacted to light and accommodation.

Defæcation.—The bowels usually act regularly once a day. There is no conscious desire to defæcate beyond what he describes as an occasional "rolling" in the abdomen. He never exerts any effort, nor is there knowledge of the passage of the fæces. Only when there is looseness of the bowels is there any incontinence.

Micturition.—Ordinarily this occurs during action of the bowels once in 24 hours at about 8 o'clock in the morning. He asserts that usually he does not again micturate till the same time on the following morning, but as a precaution he generally gives himself the opportunity to pass urine at about 4 o'clock in the afternoon as well, but often without result. Only in the event of his taking more fluid than usual and failing to take the precautions he has learnt by experience to be necessary is there incontinence of urine. There is never desire to micturate.

Finally, he seems to be without most of the common emotions. He is without family affection—the fact that he believed his mother to be dying in no way disturbed him. He makes neither friends nor enemies. He has no love of country or home. But he would appear to be a smart and efficient soldier and takes a pride in it. He was always very active, ready, and willing to help in hospital duties.

Diagnosis.—A few words may be said as to diagnosis. The most satisfying explanation of the thermic insensibility would be the existence of syringomyelia. The fact that the condition of the patient is practically congenital is compatible with the developmental nature of the spinal lesion in this disease. It may be objected that the motor system is so far unaffected, but the course of the disease is well known to be very slow. Osler, in his "Practice of Medicine," notes one of the types of syringomyelia described by Schlesinger in his monograph (1895), to which this case would in some measure conform—"with predominant sensory features, simulating hysterical hemiplegia, *or with general pain and temperature anæsthesia.*" At the same time there are certain inconsistencies in the clinical picture which point to a possible admixture of hysteria. He is a good swimmer, which implies the performance of regular coördinated movements of the legs without visual control. Yet on being invited to perform movements of the arms with closed eyes he was completely at a loss. He was also able to walk with eyes shut. The diagnosis of syringomyelia combined with hysteria is therefore suggested as one which seems to meet the case.

THE PREVENTION OF RELAPSE OF HYSTERICAL MANIFESTATIONS.

BY T. A. ROSS, M.D. EDIN.,

TEMP. CAPTAIN, R.A.M.C., MEDICAL OFFICER IN CHARGE OF A DIVISION AT SPRINGFIELD WAR HOSPITAL.

THE first essential in the treatment of hysterical manifestations is accurate diagnosis, as has been pointed out by Fearnsides and others.[1] Without going over the debatable question of reflex paralysis described by Babinski and Froment, it is necessary to remember that many patients who present hysterical manifestations show signs of organic lesions also. In many whose chief symptoms have a psychological origin, readily removed by psychical treatment, a gross organic lesion is present, situated anywhere between the cerebral cortex and the periphery, giving rise to less prominent manifestations, and naturally remaining uninfluenced by psychical treatment. Putting aside these cases, and they form by no means a small percentage of the total admissions to every hospital at which cases of functional nervous disorder are treated, and dealing only with those patients in whom the manifestations are wholly of functional or "hysterical" origin, the question arises whether the removal of the obvious symptoms is the same as the "cure" of the patient; on clinical grounds it is certain that the two are not identical.

For the first few days after the removal of gross objective disabilities, patients, who have been admitted suffering from a functional nervous disorder, are usually genuinely pleased; they have a sense of increased well-being and are deeply grateful. Later, however, many complain that they are not feeling so well. If asked how they are, many will say "My head is bad," although headache may not have been a symptom previously complained of; or they may reply that they do not feel so well in general condition as when they were admitted. When making inquiries of this sort it is needless to say that care must be taken not to suggest to the patient any symptom, such as headache. But if the patient be asked in the most general terms how he is, especially if the question be put in a cheerful tone, in a manner which anti-

cipates a favourable reply, it cannot be said that any suggestion has been made. Now it is undoubtedly true that the majority of medical men who treat and rapidly remove hysterical symptoms by methods which depend on some form of suggestion alone, hold a contrary view. They teach that the "cure" of the symptom is usually followed by improvement in general well-being. From a study of the published works of those who hold this view it may be assumed that the explanation of this discrepancy is, that after the symptom has been removed, these authors do not apparently think it wise to question the patient further. Contrary to what is usually believed, if the neuropath be not questioned, the doctor will not be told much; these patients do not talk about their symptoms to those whom they do not consider interested. A recent writer[2] has even gone so far as to state that "there is no such thing as hysteria apart from hysterical symptoms." One holding this view could hardly be expected to probe far, after such symptoms were removed. In another work dealing with the rapid cure of hysteria by persuasion[3] the same author states that "so far as we know relapses have not occurred after discharge (from hospital) except during air raids among men living in London. This is an additional argument, if any are still necessary, for the removal of all patients, officers as well as men, suffering from war neuroses out of London." It is, however, more than possible that it is an argument that the method of persuasion which this author employs is inadequate, and indeed an argument that there is something in hysteria besides the symptoms.

The removal of hysterical symptoms in these war cases is not difficult. Any doctor who will take the trouble to listen attentively to the whole story which the patient tells, who makes a careful, complete clinical examination, who is able to make up his own mind definitely that the symptoms have a functional origin, and who then so expresses himself that the patient becomes aware of all this, will be rewarded by the speedy disappearance of these symptoms. Some doctors seem to be fortified by the use of aids such as electricity, hypnotism, or manipulations; others by making the patient half drunk. But none of these things are necessary, and in the end most of them are harmful. The simple explanation that it is want of confidence on the patient's own part which is keeping the symptom still in existence, and very quiet directions telling him what to do will suffice, provided that all the foregoing conditions are observed.

At this stage, however, the patient is not cured. He is not yet cured because that which underlay the hysterical manifestation has not yet been touched. Two undesirable happenings may ensue: either (*a*) the patient may begin, or continue, to complain of other symptoms, such as headache, or (*b*) during some time of emotional stress, such as an air raid in London, the symptoms may reappear. Much can be done for the latter contingency by prophylactic education. Every patient should be instructed that in the future, and at any time, his symptoms may return as an emotional reaction. Should this happen, and he recognises that it is analogous to a transitory flood of tears, it will not persist, and little inconvenience will be caused. If, on the other hand, he thinks that the dread disease has returned because he was not fully cured, the want of confidence which such a thought engenders may prolong the reaction indefinitely. Then his state will be as it was before the "cure."

G. R., after an attack of "trench fever," suffered from tremors so gross as to prevent him walking. He was treated for several weeks in France with rest in bed; then he was evacuated to England, and in a single hour the tremor and difficulty in walking were "cured" by persuasion, but no explanation was given. Two months later he returned to his depôt. There he immediately collapsed and remained in a state of complete astasia-abasia till he could obtain further treatment.

This case may be contrasted with that of D. McH., who was admitted to hospital suffering from a flaccid, hysterical paraplegia. He was cured by persuasion, and the nature of an affective response was explained. One night a few weeks later there was an air raid. The patient wanted to get up in order to go to the subway, to which any patient may proceed on such occasions. To his surprise he was unable to move his legs. Remembering what he had been told, he thought for five minutes of the explanation, which to him had been given previously; then he got up and walked to the subway.

An air raid and a return to depôt are both events associated with emotion; he who cannot stand the one is not likely to stand the other. For the success of the method, the means employed must be of the simplest. The man must be convinced that it was he himself who worked the "cure," or he cannot hope in future to "cure" himself. It is impossible to make use of this method if the man has been treated with electricity or manipulations, &c. For then he is certain to believe that it was the "agent" which effected the "cure." But if all that the medical officer did was to tell him that he was able to talk or to walk, and he thereupon did so, he can reasonably hope to repeat the "cure" by himself if necessary. Experience proves that he usually can do this. Care must be taken that the "cure" does not occur whilst the patient is being so much as touched. Thus a dumb man unfortunately recovered his speech while his throat was being examined with a laryngoscope. This patient relapsed, and was unable to "cure" himself because he believed that the mirror had been the instrument of "cure," and that the use of some objective apparatus was essential.

A better way to prevent relapse, better because it deals also with the concomitant symptoms, is to find out why the patient ever had an hysterical symptom at all.* There is something in hysteria besides the symptoms; there is evidently some special tendency for the patient to react in this abnormal way; there is always a series of other symptoms, such as headache, insomnia, &c. The individual is out of harmony with his environment, and inquiry will show that the mal-adaptation is psychical. He has some trouble, and this must be brought to the surface. The object of this is simple. When two people discuss a difficulty, a reasonable view of it is more likely to be taken than when it is brooded over alone. After such a discussion the patient looks at his trouble in a different and happier way. Moreover, some idea may be brought to light, some thought which had determined the form taken by the hysterical manifestation, and this will impress on him the more how he may become the master of his health.

A. D. had total paralysis of the right arm, which hung like a flail by his side. It had come on suddenly one morning at dawn eight months previously; he had been on duty all night in an observation post, and had just been relieved. He was climbing out of the post, using this arm to pull himself over a parapet, when the arm became paralysed and he fell back into the trench. He could not account for it in any way. By a process of thinking back he was soon able to recollect what had been in his mind at the moment the arm gave way—viz., that this morning was lighter than usual, and that he might be seen and sniped. The proof that the symptom had occurred, not as a result of disease, but as a pure "defence," was now made very clear to the patient, who returned to duty in a few weeks.

Not always will anything so striking as this be discovered, but with careful inquiry some point of psychical importance will be found, most often of a nature which has caused pain to the patient—fear that he has been a coward, that he will become insane, that he will suffer much disability in future—needing only discussion to be dissipated. To obtain this information time and patience are essential; most of it can be got by ordinary conversation, and the proper taking of the history. The best description of the way in which this should be done will be found in Déjerine and Gauckler's Psychotherapy.[4] Rarely will it be necessary to employ more difficult methods than those there laid down, for these matters have not as a rule been so pushed out of consciousness that ordinary conversation will not reveal them. With patience events that have not been thought of for as many as 20 or 30 years may be brought to light. Should, however, this simple method fail we need not be afraid of psycho-analysis. We shall not as a rule, unless we are looking for them, be troubled with distressing sexual matters, as Rivers has shown.[5] The method is, however, rarely needed; time and gentleness yield an amount of information incredible till they have been tried.

When we have relieved the patient's mind by getting him to see his trouble in a different light it will be found that his capacity to withstand emotional reactions, such as those brought about by air raids, thunder, or the return to duty, has so much increased that he no longer meets them by the feeble defence of an hysterical symptom.

I have to thank Major R. Worth, R.A.M.C., for permission to quote the cases mentioned in this paper.

ON ABDOMINAL EVACUATION OF THE PREGNANT UTERUS BEFORE VIABILITY.

BY VICTOR BONNEY, M.S., M.D., B.SC. LOND., F.R.C.S., M.R.C.P.,

ASSISTANT GYNÆCOLOGICAL SURGEON TO THE MIDDLESEX HOSPITAL; SURGEON TO THE CHELSEA HOSPITAL FOR WOMEN, ETC.

THE appreciation of the fact that an incision through the uterine wall, provided the uterine cavity is not infected, can be stanched of blood, sutured, and got to heal with perfect security and safety has immensely enlarged the scope of hysterotomy.

Practically restricted in the older days to the timorous performance of Cæsarean section, it can now be employed not only for the abdominal delivery of a living child, but for the enucleation of fibroids, single or multiple, deeply embedded in the uterine wall, for the exploratory opening up of the uterine cavity in cases of menorrhagia or metrorrhagia of obscure origin, and for the extraction of the products of gestation before viability. It is with this latter application of hysterotomy that I now deal.

Conditions in which the Operation is Indicated.

What are the circumstances under which it is preferable before viability to empty the pregnant uterus through the abdomen? In the main there are three sets of circumstances, as follows:—

1. *When in addition to evacuation sterilisation of the patient is required.*—In certain cases of pregnancy in tubercular women the uterus should be emptied at once and further pregnancy prevented by ligaturing or removing the tubes. As a typical case of this sort I may instance that of a woman who, having had several children, developed acute phthisis whilst carrying the last one. Treatment in a sanatorium resulted in recovery sufficient enough to allow her to return to her home and household duties, when she promptly became pregnant once more.

Again, in valvular disease of the heart with compensation, already trembling in the balance, pregnancy should be arrested as soon after its initiation as may be feasible, and further conception rendered impossible.

Much rarer than these two instances are those cases in which pregnancy is habitually followed by some dangerous disturbance of the economy, as, for instance, by nephritis, diabetes, hæmolytic anæmia, or insanity. In all of these evacuation of the uterus should be combined with a sterilising operation. Finally, cases of physical deformity incompatible with continued pregnancy are sometimes met with, such as extreme kyphosis.

The older course in all these cases was to first evacuate the uterus through the cervix or to induce abortion, and then to open the abdomen and ligature or remove the tubes. I have abandoned this practice for some years, believing it to be faulty, more especially if the pregnancy has advanced beyond the third month, and, having opened the abdomen, I now deliberately incise the uterus through its anterior wall, shell out the pregnancy, close the uterine wound with three mattress sutures and a superficial continuous suture, and then ligature and cut off the outer halves of the tubes. By this means the proceeding is shortened and simplified, and, moreover, rendered absolutely aseptic, for the uterine interior is sterile to start with, and, for the rest, I have the factors that will keep it so entirely under my command. It is doubtful to my mind whether evacuation through the cervix can ever be carried out without introducing some organisms into the uterus whilst the commonly used means of inducing abortion, the bougie and tent, almost certainly act as organismal conveyers.

2. *When the pregnancy has advanced to the fourth month or over and its termination is urgent.*—The evacuation through the cervix of a pregnancy of five or six months' standing is a formidable operation. The extraction of a head of even four months' growth needs a degree of cervical dilatation which almost always splits the cervix. At five or six months sufficient dilatation cannot be obtained even by deep splitting, and the surgeon is obliged to incise the lower pole of the uterus along its anterior wall from the external os upward to the peritoneal reflection—the so-called vaginal Cæsarean section.

Vaginal Cæsarean section is an operation for the expert alone, particularly in women who have not previously borne children; but its greatest drawback is that it inflicts a wound in the uterus through a passage (the vagina) that cannot probably with certainty be rendered initially sterile, and certainly not kept sterile during an operation of some duration.

For these reasons I have for a long time now adopted the abdominal route for the removal of a pregnancy of four, five, or six months' standing in cases of gastro-hepatic or cerebro-renal toxæmia (pernicious vomiting and eclamptic nephritis) or such other gravely menacing complications of pregnancy.

3. *In certain cases of pregnancy complicated by fibroids.*—Every now and then one comes across cases of early pregnancy complicated by fibroids in which the tumour or tumours force surgical intervention. It should be a cardinal rule in the surgery of fibroids that whenever the uterus bearing them is also pregnant the removal of the organ should be avoided if possible—it has proved its domestic and national value.

Now the uterus nearly always can be spared. Pedunculated fibroids can be removed and the pregnancy left *in situ*, abortion only rarely following. But this is not so if the tumour or tumours be embedded, for then their removal alone will almost certainly be followed by abortion. Moreover, the suture of the cavity or cavities left in the uterine wall after the enucleation is not likely to be satisfactory if the organ be still distended and vascular from the pregnancy within it, and further, if the organ empties itself within the next 48 hours there is a considerable chance of intraperitoneal bleeding from the blood-stanching sutures becoming loose. For this reason it has been the custom to remove the pregnant uterus with the fibroids in such cases.

But why not treat the pregnancy like another fibroid, enucleate it too, and leave the patient with her still competent organ? She can, and will, become pregnant again *minus* the disability of concomitant myomatous growth. Fears may be entertained that the scarred uterus will not stand the strain. They are groundless. Of all tissues I believe the uterine muscle has the most perfect healing powers. You can never find the uterine scar of a previous Cæsarean section when you open the abdomen to perform the operation for a second time, and I have had two opportunities now of viewing a pregnant uterus on which I had previously done myomectomy, and the same was true.

Conclusion.

In conclusion, then, I feel sure that under the several circumstances I have detailed, the early pregnant uterus should be evacuated through the abdomen.

The technique is just that of a Cæsarean section, than which it is an even easier operation. The uterine incision needed is smaller, of course, the bleeding is less, and fewer mattress sutures are required to close the hole and stanch the blood-flow. I use silk (No. 4) for these sutures, and insert a continuous suture of No. 2 30-day catgut to bring into apposition the peritoneal edges: these stitches should pass deeply. One c.cm. of pituitrin should be given just before the operation and repeated during the suture of the uterus. The incision should always be made through the *anterior wall* for two important reasons: first, so that the uterine wound may present towards the bladder and thus avoid adhesion to the intestine; and, secondly, so that if persistent oozing goes on from the needle punctures the uterus can be fixed to the anterior abdominal wall by two or three silk sutures along the line of the uterine incision. Oozing from the uterine incision or needle punctures is dangerous, because the effused blood attracts coils of intestine to adhere to the uterus.

Before deciding that oozing from these sites is really persistent, put the uterus back into its place and watch it for a minute or so. So long as it is outside the abdominal wound it tends to bleed, because the venous return is interfered with by the traction on the broad ligaments and the nipping of the abdominal wound edges. In this regard the uterus is like the kidney pulled through a loin wound; moreover, no uterus will retract perfectly until it is back in its proper place.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF POLIO-ENCEPHALITIS TREATED WITH NOVARSENOBILLON.

BY ERIC BAYLEY, M.D. LOND., F.R.C.S. ENG.;
AND
ALFRED G. SIMMINS, M.B., B.S. LOND.,
SURGEON LIEUTENANTS (TEMPORARY), R.N.

IN the following case the improvement in symptoms after N.A.B. treatment and lumbar puncture was very marked. It is difficult to say to which the patient owed most. The lumbar punctures relieved the pressure symptoms, but the progress might not have been so rapid without the N.A.B.

On June 27th a leading telegraphist, living ashore, was admitted to a naval hospital ship in home waters, suffering from headache, slight fever, and persistent vomiting of cerebral type. The optic discs appeared normal. Lumbar puncture was performed and 50 c.cm. of clear fluid under increased pressure were withdrawn. The fluid contained 400 cells per c.mm., nearly all small lymphocytes. No micro-organisms were discovered.

In the next few days further cerebral symptoms developed. Nystagmus, squint, retraction of head, Kernig's sign, absence of knee-jerks, and extensor plantar reflexes were noted. There were no signs of cerebral irritation, and apathy was a distinctive feature. Temperature never rose above 100° F. A second lumbar puncture carried out when these symptoms were at their height yielded a result identical with the first. The diagnosis at this stage was by no means clear. It rested between syphilitic or tuberculous meningitis and epidemic polio-encephalitis. Examination of the cerebro-spinal fluid had excluded cerebro-spinal meningitis.

Six months previously patient had acquired syphilis. The diagnosis was made by examination of exudate from primary sore by dark-ground illumination, and no secondary lesions were seen. He was treated with 1·9 g. of galyl given in six doses at weekly intervals, the last dose being given on March 12th, 1918. Grey powder, six grains per diem, was given from May 20th to June 20th, and, at the time of admission, the patient was suffering from severe mercurial stomatitis. No record of any Wassermann test was found in his service syphilis sheet. In view of this history the question as to whether syphilis was the cause of the present illness had to be carefully considered, particularly as several severe recrudescences of syphilis in patients treated with galyl had been seen by one of the writers during the last two years.

The blood serum and the cerebro-spinal fluid were therefore sent to Haslar for the Wassermann test, and in the meanwhile treatment with novarsenobillon (N.A.B.) was begun. Following the combined treatment by these injections and by lumbar puncture, there was decided improvement. The apathy cleared away, squint and nystagmus disappeared, and the speech, which had become slow and indistinct, rapidly improved. No difficulty in swallowing had been present at any time, nor had there been any salivation or dryness of mouth.

The report on the Wassermann tests was negative for both serum and fluid. Two interpretations could be attached to this report: either patient was free from syphilis, or so few spirochætes were present that insufficient reacting substance had been formed in his body to give a positive reaction.[1] If the latter hypothesis be adopted it may reasonably be supposed that such a slight syphilitic affection could not give rise to the severe symptoms exhibited by the patient. Syphilis may therefore be excluded except as a possible predisposing cause.

A third lumbar puncture, performed when patient showed signs of improvement, produced a fluid having only 60 cells per c.mm. The injections were then stopped as patient continued to make satisfactory progress. Recovery was uninterrupted and in less than a month from the date of admission he was sitting up in a chair playing draughts, reading books, and writing letters. From a detailed report kindly supplied by the Medical Director Commanding a U.S. Naval Base Hospital, to which the patient was discharged, it appeared that satisfactory progress was maintained. The Wassermann test was negative in cerebro-spinal fluid on August 8th and in the blood on August 8th and 13th. 38 cells per c.mm. were present in the fluid on the 8th.

The rapid recovery excluded the diagnosis of tuberculous meningitis, and the absence of signs of cerebral irritation favoured the final diagnosis of polio-encephalitis.

Cerebro-spinal Fluid.

Date.	Quantity.	Reducing substance.	Globulin.	Total proteid.	Cells per c.mm.	Wassermann reaction.

Interest centres in the pathology of the cerebro-spinal fluid. A large excess of small lymphocytes is found in the fluid in syphilis of the central nervous system, in tuberculous meningitis, and sometimes, though not in the acute stage, in cerebro-spinal meningitis. It is also found in acute polio-myelitis, and presumably, therefore, may be found in association with acute polio-encephalitis. On the other hand, in a fatal case of polio-encephalitis under the care of the writers, of which the diagnosis was confirmed at autopsy, the fluid was clear and free from excess of lymphocytes.

The writers beg to acknowledge the courtesy of Surgeon Commander C. L. W. Bunton, R.N., by whose permission the case is published.

ACUTE PNEUMONIA FOLLOWED BY PNEUMOTHORAX; FEMORAL THROMBOSIS; RECOVERY.

BY REGINALD G. HANN, M.R.C.S., L.R.C.P. LOND.,
FORMERLY MAJOR, R.A.M.C. (T.)

Emerson, in his exhaustive monograph on pneumothorax, says that pneumonia was early considered a cause of pneumothorax, and that it was not until Skoda "had emphasised the presence of the hyper-resonant note, suggesting air which is present in pneumonia and in pleurisy, over the not-yet-involved lung that these cases were recognised as not pneumothorax." Its rarity is shown by the fact that in Biach's collection of 918 cases of pneumothorax not one is ascribed to pneumonia, and that in 7868 cases of pneumonia which formed the basis of a discussion on the complications of that disease at the Royal Society of Medicine only three cases (two fatal) are to be found. Nor is this rarity a matter of surprise, for the alveolar consolidation of pneumonia would appear, on theoretical grounds, to act as a bar to such an accident.

In the present case it is significant that there was a history of winter cough, and however trivial it may have been and the anatomical change causing it, it certainly suggests the rupture of an emphysematous bleb.

An infantry private, aged 35, prior to enlisting in January, 1916, had worked as a tram-driver, necessarily exposed to all weathers. He had had no illness of importance, but a winter cough kept him from work occasionally, though his average loss of time did not exceed two or three days per year; during his first two years in the Army he was never ill.

Early in April he was in the front line in Flanders under very bad weather conditions, being continuously cold and wet; he felt ill, but kept on until the onset of a rigor, and then went to hospital. His record shows that he had a right lobar pneumonia running an ordinary course, with a crisis on the sixth day (April 18th). He improved, crossed to England, and was admitted into hospital under my care.

The following are the notes of his condition:—

April 23rd: Looked and felt ill, complained of pain in chest and shortness of breath. Right lung: impaired resonance apex and base with redux crepitations at base and a few rhonchi elsewhere. Increase of V.R. and V.F. Left lung normal. No bronchitis. Heart normal in size, position, and sounds. *The signs were those of a normally resolving pneumonia.*

April 27th: Has not improved as a pneumonia should in the time; pain in chest; dyspnœa. Signs at apex as before: at base indefinite (he was too uncomfortable for prolonged examination). Heart apex is now 1 in. outside nipple line.

April 29th: Respiratory movements and inspiratory retraction of intercostal spaces equal on the two sides. Right side tympanitic from apex to level of sixth space in nipple line and lower in axillary line. Behind tympanitic at base; note doubtful at level of scapula. Amphoric breathing and beautifully clear and numerous tinkling metallic sounds were heard over whole of right lung, except posteriorly in scapular region. They were loudest in front in axillary line below nipple level and behind over lower lobe; at apex, and above clavicle even, amphoric breathing was clear, very high-pitched and distant. Whispered voice sounds clear and metallic. No moist sounds; no signs of pleural effusion. Sputum profuse, blood-stained, ropy; no tubercle bacilli found. Heart further displaced to left; its right border is level with the left edge of the sternum. *The signs were those of extensive pneumothorax with considerable air-entry into the collapsed lung.*

May 2nd: General condition improved; less pain; sputum more profuse, more frothy; no blood.

May 4th: Whole of right side of chest tympanitic. Inspiratory indrawing of intercostal spaces most pronounced on right side; bulging of spaces on right side during coughing or forced expiration. Breath sounds almost inaudible from apex to nipple level, below this amphoric breathing present; no metallic tinkling, no coin sound. Posteriorly whole lung area tympanitic with almost entire absence of breath sounds. The physical signs had therefore again changed; the silent area had largely increased and area of amphoric breathing diminished. *The signs were those of lessened lung expansion and of an increase in volume of the air in the pleural cavity.*

May 6th: Right side almost entirely silent; cavernous whispering sounds at base. Blood examination: No leucocytosis, nor did white cells suggest any inflammatory process. Liver not displaced.

May 16th: Left femoral thrombosis after a premonitory day's pain in leg; swelling of leg and thigh, skin blue-grey, much pain, pyrexia. Chest: Little change; if anything there was less evidence of air entry into right lung, though excursions of chest wall were as great as on left side. Increase downwards in silent area; no protrusion of intercostal spaces on expiration or on whistling. Pulse small, low tension, feeble. Heart sounds poor.

May 22nd: Practically no breath sounds were to be heard on right side, except about root of lung posteriorly.

June 6th: Right side of chest in front absolutely silent. Hyperresonant.

June 8th: General condition began to improve. Vesicular murmur heard in axilla and about base of lung; deep breathing increased area over which this was heard. Heart displacement as before.

June 29th: Leg recovered; no swelling; some discolouration. Easy passive movements commenced. Breath sounds heard faintly over wide area; also for first time pleural friction sound in front and in axilla.

July 28th: Breath sounds heard over whole of lung, but, generally speaking, were fainter and more distant than on left. Is able to stand out of bed.

From this date his recovery though very slow was continuous until by Sept. 2nd the only abnormality recognisable was a suggestion of distance in the breath sounds then to be heard throughout right lung; the heart had regained its normal position.

Summary.

This case afforded an excellent opportunity of observing a pneumothorax due to a rupture—probably valvular—of the pleura during coughing from its gradual onset to its practical cure—a period of over four months. The slow and deliberate increase in the amount of air in the pleural cavity with the concurrent collapse of the lung was easy to follow, distinguished as it was by its classical signs; its fullest extent was not reached until about three weeks from the onset. To what extent its course was modified by the resolving pneumonia no indication was afforded. This was succeeded by a stationary period of another three weeks before the first signs of vesicular breathing reappeared (i.e., about June 8th—six weeks from the onset). The characteristic auscultatory signs of pneumothorax were only to be heard for about 10 days (from the third to the thirteenth of the disease). The exquisite metallic tinkling was of short duration (a few days) and appeared in the absence of any pleural effusion. The behaviour of the heart in its displacement was a typical instance of its sensitiveness to any change in intrathoracic pressures; it was almost the first warning to be recognised of the grave happenings in the chest, and only towards the end of convalescence was its normal position regained.

Some Former Recorded Cases.

1. Graves (*Dublin Journ. of Med. and Chem Sci.*, 1834; quoted from Emerson, *Johns Hopkins Hospital Reports*, 1903): Man aged 40. On the fourth day of dulness lower down, from the clavicle to below the nipple, percussion yielded a "preternaturally clear and hollow sound." Physical signs of pneumothorax disappeared in about 16 hours. One is not surprised to find that the diagnosis in this individual has been doubted.

2. Rumpf (from Emerson) (Beitrag zur Lehre vom Pneumothorax, 1849): Pneumonia followed by bronchiectasis, with gangrene and pneumothorax.

3. Monnerei (from Emerson) (*Arch. gén. de Méd.*, 1851): Acute pneumonia, gangrene, perforation followed by hydropneumothorax. Death.

4. F. Taylor (in a discussion on a case of West's at the Clin. Soc.; report from *Brit. Med. Jour.*, Dec. 22nd 1883): Acute pneumonia followed by pneumothorax with some effusion; air gradually absorbed. Patient remained well for 12 months, then phthisis followed hæmoptysis. "It became a question whether the pneumothorax had been set up by the pneumonia or whether it was a result of the individual's phthisical tendency."

5. Oldridge (*Brit. Med. Jour.*, Dec. 25th, 1915): Man, aged 40, seen Oct. 6th, diagnosis pneumonia, 10 hours later more urgent symptoms; dyspnœa and cyanosis. Symptoms of shock. Right pneumothorax present; displacement of heart (?). No pleural effusion; no tubercle bacilli found. Bed 10 days; return to work Nov. 4th—i.e., within one month.

6. S. Matthews (*Practitioner*, July, 1918): Measles; whooping-cough; pneumonia; pneumothorax; recovery. Girl, aged 7. Measles, Jan. 1st; apparently well and downstairs Jan. 20th; whooping-cough Jan. 31st; broncho-pneumonia Feb. 10th. On March 10th, after coughing, sudden access of pain left lower back of chest. Pneumothorax diagnosed. March 11th: Apex beat in right axillary line. April 14th: Physical signs of pneumothorax gone. Apex normal site. No effusion. No T.B.

To these may be added (7, 8) two known cases (one fatal) in the London Hospital in a period of about ten years and another fatal case (9) in the Middlesex Hospital.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—The two Goldsmid Entrance Exhibitions, offered annually for competition in September, were awarded this year to H. Spibey, Cambridge University, and Miss J. K. Gatty, London School of Medicine for Women and King's College, London

Medical Societies.

MEDICAL SOCIETY OF LONDON.

Presidential Address.—Demonstration on Degeneration in Art, Science, and Literature.

A MEETING of this society was held on Oct. 14th, when the incoming President, Major A. F. VOELCKER, R.A.M.C.(T.), delivered his presidential address, in which he considered some ways in which the society could contribute towards the regeneration of the profession. No man could be satisfied with the position which our profession now occupied either in the eyes of the public or as a factor in the general commonweal, and he thought we had ourselves very largely to thank for this want of recognition. Our services were not understood, and consequently not appreciated, our readiness to work without remuneration was exploited, and in matters where professional knowledge was essential we were not consulted or were inadequately represented. The medical profession had allowed, and was allowing, itself to be exploited by almost every branch of social reform. The time was surely at hand when matters which affected the health and with it the morals of the community should be dealt with primarily by our profession, whilst the means and machinery for carrying out such measures might be left to the politician and social worker. In the regenerated medical profession he would urge the Fellows of the Society to be prepared to take their part as leaders in the fields of activity concerned.

Ministry of Health.

We were promised in our regenerated medical world that the health of the community, which had been up to now no one's concern in particular, though the burden had been on medical shoulders, should be the special care of a Ministry of Health. The creation of such an office would, he trusted, be the means of coördinating much of the work which was being undertaken by individuals both within and without the profession, and so preventing overlapping and redundant activities, and might even secure for our profession a recognition of the value of the advice given and the work which was constantly being done by us for the welfare of the community. At the present time the State by certain of its departments did give us invaluable help in dealing with some of the problems of infectious diseases, sanitation, and the inspection and control of food and drink, but even in these matters it must be confessed that we did not all see eye to eye with the official mind and that a Ministry of Health might possibly prove a King Stork in place of our present King Log. A Ministry of Health implied a Minister of Health, and it would be "a consummation devoutly to be wished" should such a Minister be a man (or should he say super-man) appointed by His Majesty after *election* by the qualified medical practitioners of the United Kingdom. We had lately been urged to secure the return of medical men to Parliament, but whilst recognising the excellent service such men had rendered in Parliament, could we seriously say that even a Fifth or Medical Party in Parliament would add to its utility, however much it might contribute to the diversity of the division lists? It had always seemed to him that the less medical men had to do with professional politics the better. We must be prepared for a Ministry of Health and must see to it that it was given loyal support in everything which made for the health of the community, and that the Minister was the selection of the profession and not of party.

Specialism in Medicine.

A Ministry of Health could not ensure health. The personal factor in medicine would ever be the moving power, and we ourselves must take our individual part in the practice and inculcation of the moral virtues of temperance, patience, charity, and sympathy. One of the questions in the near future would be that of the place of specialism. By many specialism was held to be the crowning mercy of medicine, but there were others who would urge that specialism was an overgrowth, and as such needed repression. There was no doubt that the public were obsessed with the glamour of specialism. If we thought of it we should recognise that in this matter of specialism it was the public and not the profession which created and supported the specialist, and he urged that this

was not desirable. In a regenerated condition of medicine might we not hope that specialists would be those who by their work and ability had won the confidence of the medical profession, and that the practice of specialists would flow to them through the channel of the practitioner and not through the press or the public. In the new earth (he dared not say new heaven and new earth) of medicine we must beware lest specialism be allowed to occupy too prominent a place. There would always be the need for specialism, but the specialist must follow and not precede the generalist. It would be one of the dangers of a State-controlled medicine, should that come, that the popular clamour for specialism might lead to the multiplication of special hospitals or special departments in hospitals and that the coming race of medical practitioners would be lamentably deficient in general knowledge.

A State Medical Service.

The question of the creation of a State Medical Service was one which was certain in the immediate future to claim the serious attention of our profession: for years we had seen it coming, though few had leaped for joy at the prospect. Financial burdens, due largely to the increased cost of treatment and maintenance, though not to the payment of the medical men, had compelled the managing bodies of our hospitals to realise that some change must take place in the financial resources of our hospitals if these were to carry on their work efficiently. It was felt by many that the work done was for the good of the State, and that, consequently, the State should pay for the work for which certain sums of money were voted annually by Parliament. The State, through such agencies as the Local Government Board, the county councils, the Universities, and the Board of Education, already granted financial aid to our profession, in order to enable provisions of public health legislation to be carried out, and with the gilding came the pill in the form of control. We were reminded that there were sums of money voted by Parliament and contributed by the taxpayer, which were available in the form of grants, and that if we did not choose to take them there were other bodies who would, and who would be enabled to compete with us under more favourable financial conditions, and—what was much more serious for our hospitals and for medical education—would be able to divert from us the material which we valued, both for its scientific and educational, as well as for its humanitarian interests. We were, perhaps unnecessarily, reminded of the fact that in hospital work we received nothing for the time and labour we devoted to the treatment of the patients, and little, nothing, or even less than nothing, for the education of the future medical practitioners, and we were told that State control of hospitals would do away with this anomaly. The bait was tempting, but it was possible to pay too dearly for financial relief. Apart from hospital work it was urged in favour of a State service that when such a system was established every medical man would be able to rely on securing a living wage in return for which he should render medical service to the individual and to the community. Undoubtedly this would relieve many a hard-worked doctor of the wearing anxiety arising from the uncertainty of practice, but the object of State service should not be to secure a definite benefit for the doctor unless a corresponding benefit accrued to the patient or the community. As long as medical men were content to work for such low fees as obtained in certain practices they would not even deserve the respect and consideration paid to those who, in their respective fields of labour, demanded a minimum wage and restrictions of hours of labour. The low fees of which he had spoken were either grossly disproportionate to the services rendered, or the services rendered were not such as a highly trained and honourable profession could justify. The question of fees was a difficult one to tackle, but he trusted that in a regenerated state of our profession a juster arrangement of fees, both in the direction of raising the low fees and in mitigating the high fees, would be brought about, and that our licensing bodies would not allow the low scale of fees at present ruling in some practices.

Criticism of State Control.

The prevention of illness might be regarded as a duty of the State, and much had already been done by the State in the direction of prevention and treatment, but none of us could say that this duty was carried out efficiently. The outbreak of the numerous centres of medico-social activity such as health centres, infant-welfare centres, after-care associations, which were the creation of non-official bodies, testified to the inadequate manner in which at present the State played its part in protecting and furthering the welfare of the citizen. Some of us felt that it would be an evil day when the State by its medical service undertook the care of the health of the individual. The profession of medicine was so eminently human and the services so personal that it might be feared that as no man could serve two masters, so no medical man could serve both the State and the patient simultaneously. Was it not possible that a State service might destroy in its officials that energy and interest which were such important factors in the attainment of success in private practice? Promotion in a State service, if it became merely a matter of seniority, would cease to be striven for, and be merely waited for, and, if made the reward of real or imagined merit, might lead to intrigue and abuse. Our experience of State control as a stimulus to originality and endeavour had not been so convincing as to its advantages as to make us enthusiastic on its behalf, and although the splendid efficiency of our naval and military medical services during the war might be advanced as evidence of the value of a State service, we must remember that the temporary incorporation of civilian practitioners into these previously State-restricted services might be the explanation of the strikingly brilliant achievements of our medical services in this war. Advancement by merit in a State service would be a very questionable method of procedure.

Concluding Remarks.

He hoped that the medical profession would see to it that the remuneration of nurses whose work was so essential to the success of our treatment, and whose labours were so ungrudgingly given, should no longer be on a scale which was a scandal to our profession, for it was *we* who stood by and saw the miserably inadequate salaries paid both in hospitals and in private to the nursing profession. In his opinion, a woman who took up nursing took ten years off her life. After training three or four years she was then, worked out, able to earn a wage which a parlourmaid would scorn. During her training she was housed and fed, worked hard, and got possibly £12 in her first, £18 in her second, and £24 in her third year. Out of this she had to clothe herself and provide for a holiday and any recreations. For her there was no 8-hours day, any more than there was for us.

This society was founded "to give practitioners in medicine frequent opportunities of meeting together and conferring with each other concerning any difficult or common cases which might have occurred, or communicating any new discoveries which might have been made either at home or abroad." In his remarks on the occasion of the presentation of the first Fothergillian medal Lettsom defined the duties of the practitioner of medicine, surgery, and pharmacy, and observed on the importance of an institution which associated the respective members of each. Lettsom's interests were catholic, his activities ceaseless, and were all directed to the welfare of others.[1] He was an original member of the Humane Society; his voice was raised in favour of measures for preserving the health of prisoners in gaols and preventing the gaol distemper; he was instrumental in raising the Howard memorial; he was the first to send Jenner's vaccine to America; he instituted the Royal Sea-Bathing Infirmary at Margate; he founded a society for the cultivation of bees. His generosity and hospitality were proverbial. He was intensely human. He was not afraid to denounce quackery, as was seen in his ruthless exposure of the urine caster Myersbach. His energies were constructive as well as destructive, and while he was busy lashing the latest fashionable quack he was devising means for increasing the supply of bread by the addition of potato, and of encouraging the cultivation of the mangel wurzel as an additional source of food. It was on the labours of such a man that we were entered, and he thought that we could fairly claim that the success of this society had been its loyalty to the traditions of its founder.

Dr. T. B. HYSLOP gave a lantern demonstration illustrating the Oration on Degeneration in Art, Science, and Literature which was delivered last session. The demonstration consisted of pictures composed by various types of degenerates.

[1] THE LANCET, 1918, i., 70.

Reviews and Notices of Books.

Surgical Therapeutics and Operative Technique. By E. DOYEN. English edition, prepared by the Author in collaboration with H. SPENCER-BROWNE, M.B. Cantab., &c., Élève de l'Institut Pasteur; Physician to and Chef de Clinique de l'Institut Doyen. Vol. II, pp. 680. With 982 figures in the text. London: Baillière, Tindall, and Cox. 1918. Price 25*s.*

THIS is the second of the three volumes of which the English edition of Doyen's work is to consist. The first was reviewed in THE LANCET of June 9th, 1917 (p. 881). The volume now before us contains the continuation of the section dealing with operations on the head, as well as those concerned with the neck, thorax, upper and lower limbs. This volume is no less characteristic of the views and methods of the accomplished author than was its predecessor. The wealth of illustration is the most obvious feature. The drawings are all admirably clear and well executed, and a very large proportion of the figures are reproductions of photographs, as was to be expected in a treatise by one who had brought into such prominence the use of the camera and the kinematograph for the representation of surgical technique. Yet, admirable as they are, the number of illustrations might probably have been halved without detracting from the value of the book; thus in numerous instances a general sketch of the operation is followed by an enlarged view, where one or the other could well be dispensed with; and 11 figures are surely unnecessary to illustrate the exposure of lymph-glands by divulsion. Some of the figures, too, are nearly useless, and a few are really bad. Fig. 546, for example, shows a procedure which in many hands would be dangerous, and Fig. 553, as an illustration of a method of removing cancerous axillary lymph-glands, cannot pass without criticism.

Perusal of the text suggests that the book is not one for students, but is likely to be of considerable use only for those who have already had a good deal of experience of clinical and operative surgery; for there is next to no discussion of methods other than those which the author employed, and the description of these is often very sketchy indeed. Many dangerous and some highly questionable operations are lightly referred to. Very few would regard the operation figured on pp. 246–248 as justifiable. Some operations on the mediastinum, trans-pericardial anterior œsophagotomy, resection of the cervical sympathetic for the exophthalmos of Graves's disease, and the division of posterior nerve roots for the gastric crises of tabes occur as further and striking examples. Yet many other debatable questions of treatment, such as that of removal of cervical ribs or that of thyroidectomy for Graves's disease, are far too shortly and easily disposed of. But it is good to see, in text and figures, the constant reference to topographical anatomy, which every operating surgeon ought to cultivate—a study, alas, too little fashionable at the present day. Good also is the assumption in this volume, as in the first, that every surgeon will strive to make himself an accomplished clinician; it may be for the surgeon rather than for the physician to decide the proper time and manner of surgical intervention. We see throughout evidence of the importance attached to speed in operating; even so, it is startling to read that the naso-pharyngeal tumour represented in Fig. 249 was removed in 15 seconds, or that denudation and resection of a rib need occupy only 5–10 seconds; and to see the method of transfixion in disarticulation at the hip recommended as superior to all slower methods—Liston himself could have done no better! The continued recommendation of the use of mycolysine and phymolase in septic and tuberculous infections (of the former even for suppurative arthritis of large joints) is perhaps not surprising, but is likely, we imagine, to meet with little serious study in this country. Still less likely to find adherents are the views of the author on the causation of tumours and on the value of "anti-neoplastic vaccination" and thermic electro-coagulation. Indeed, preference for such methods of treatment may have been not unconnected with the nature of the operations here recommended for carcinoma of the tongue and of the breast, operations which most surgeons would regard as partial and inadequate.

The translation is not always beyond criticism. "I have removed a Flobert bullet of six millimetres from the body of the second cervical vertebra, which had been discharged within the mouth" is an example. There are fewer misprints than might have been expected in a work of this size. An index would have been valuable.

Medical Electricity. By H. LEWIS JONES, M.A., M.D., F.R.C.P., late Consulting Medical Officer to the Electrical Department, St. Bartholomew's Hospital. Revised and edited by LULLUM WOOD BATHURST, M.D. Lond., Physician in Charge of Electrotherapeutic Department, Royal Free Hospital, &c. London: H. K. Lewis. 1918. Pp. xvi. + 588. 15*s.* net.

THE task of revising a book such as that of the late Dr. Lewis Jones has called for judgment and discretion. The difficulty has been met in what we consider the wisest way—that of leaving the work in its original form—making only such alterations as are necessary to record the more recent advances in the subject. Consequently our remarks on the previous edition[1] apply in the main to the volume now before us. The then recent developments in our knowledge of the action and uses of electrical applications have been further extended, and the whole subject has received a tremendous impetus in studying the experience gained in dealing with the various disabilities following injury and disease in the Great War. These are reflected in the additions made by the editor, but with the vast amount of material, becoming greater day by day, it is too soon to expect more than general inferences and conclusions. With regard to the use of condenser discharges for testing nerves and muscles, it appears that their value in accurately determining the degree of degeneration present has not come up to expectations, though the method constitutes a very substantial advance on the use of the coil and constant current. The extended uses of ionic medication and diathermy are enlarged upon, while the application of electrical currents through the medium of water kept in constant motion constitutes one of the most recent and useful methods. These and other matters have been brought up to date, so that the book remains the standard volume on medical electricity published in the United Kingdom. If we were to offer any criticism it would be to question the desirability of attempting to include a description of X ray appliances, their uses and applications, in a work of this kind. The subjects of medical electricity and radiology have developed so enormously in recent years that one can no longer be regarded as a sort of side issue to the other.

Quantitative Chemical Analysis. By FRANK CLOWES, D.Sc. Lond., and J. BERNARD COLEMAN, A.R.C.Sc., Dublin. Eleventh edition. London: J. and A. Churchill. 1918. Pp. 580. 12*s.* 6*d.* net.

APPRECIATION of this book on "Quantitative Chemical Analysis" is patent since it has now reached its eleventh edition, the first edition having been issued in 1891. The work has developed through this period from a manual for use in the laboratories of colleges and institutes to a volume of reference helpful to the consulting and analytical chemist. The chapters on water analysis, foods, oils, fats, and waxes, in addition to those on technical analyses, may be quoted in proof of this statement. The simple gravimetric estimations refer chiefly to the metals, and suggest really useful exercises. The technical analyses form a valuable feature of the work; it is a department of analytical practice which has evidently occupied considerable attention from the writers. Here are considered the methods of valuing ores for their metallic contents, alloys for the separation and estimation of their constituents, soda ash valuation, glass analysis, and other important directions of chemical assay. In a subsequent chapter a very useful section is given presenting the results of typical analyses made under the supervision of the authors in their laboratories. The book is thus thoroughly practical, and maintains its standard character, the manipulative details and the methods described being brought into line with modern developments.

FRENCH SUPPLEMENT TO THE LANCET*

Under the Editorial Direction of

Professor CHARLES ACHARD,
PROFESSOR OF PATHOLOGY AND THERAPEUTICS IN THE UNIVERSITY OF PARIS.

AND

Dr. CHARLES FLANDIN, D.S.O.,
MÉDECIN-MAJOR DE 2ME CLASSE; CHEF DE CLINIQUE À LA FACULTÉ DE PARIS.

FOR four years British Arms have fought on French soil for the cause of Justice and Progress. The coöperation of the Allies, at first exclusively military, has grown in scope, and has extended to realms apparently without the range of the war. An ENTENTE has been replaced by a UNION. And this Union should exist after the war, and should coöperate in all fields of human activity. Our doctors must not remain outside the great *rapprochement*, which should make one the soul of Britain and the soul of France.

British and French soldiers now make one Army, and this is because they have learned to understand each other. That the British and French doctors should become the exponents of one scientific and moral organisation, it is necessary that they should understand each other.

The aim of this Monthly Supplement in THE LANCET is to enable British doctors to understand the theories and the researches of French doctors.

We propose to issue, in more or less monthly form, a general review of some big medical subject and an original article dealing with a particular question. We shall obtain these contributions from authors whom we know to be especially qualified by their researches and work to set out ably the results actually achieved, as well as the trend of ideas in France. In this way we aspire to assist our British confrères to a fuller understanding of French medical movements, and we shall be happy to serve them by placing them in relation with those of our workers whose researches interest them specially. If this Supplement leads to mutual interpenetration of the two medical worlds we shall be amply repaid.

CH. ACHARD.
CH. FLANDIN.

WHAT THE WAR HAS TAUGHT US ABOUT TETANUS.

By LOUIS BAZY.

TETANUS is one of the diseases most anciently known. It has been besides much studied from the clinical as well as the bacteriological point of view, and everyone recalls the fine researches made in France by Roux and Vaillard, which gave us antitetanic serotherapy. It appeared, then, that the war was not able to teach us anything new. However, for the first time in our armies all the wounded received repeated doses of antitetanic serum. The result was that the common tetanus, that we were observing before the war, almost completely disappeared. In its place some cases have been observed, occurring in spite of the serum, and for this reason called by Borrel [1] post-seric tetanus. These forms present a particular physiognomy absolutely different from the classical form.

"There is, indeed, in question a tetanus of incomplete immunisation, tetanus which represents a fine example of those modified morbid types, with which preventive medicine is in course of endowing the natural history of the infectious maladies." (Widal.)

In short, it may be said that the war has brought us the following ideas:—1. Antitetanic preventive serotherapy is efficacious in the immense majority of cases. 2. When it acts incompletely it so modifies the course of tetanus that it has created new forms of the disease, unknown before its use was general. 3. The study of the checks to serotherapy ought to lead us (*a*) to use the serum in a more rational way; and (*b*) to know how to complete its action by that of an antitetanic vaccination. These are some points that it is proposed to consider.

I.—*Efficacy of Antitetanic Preventive Serotherapy.*

Before, and even during, the war some surgeons have discussed the efficacy of the preventive serotherapy of tetanus. It is, however, beyond discussion. Pierre Bazy,[2] who, the first, in 1914 proposed to make systematically in all the wounded an injection of antitetanic serum, has only observed 129 cases of tetanus in 10,896 wounded in hospital in the entrenched camp of Paris. These cases were almost entirely seen where the preventive injection was not habitually practised. Walther[3] received at the Val-de-Grâce 200 wounded Germans. The serum not being available at this moment in sufficient quantity, 100 cases only could receive an injection. One alone had tetanus, which appeared the day after admission—i.e., the prophylactic injection had been made too late. Of the other 100 who had not been injected 18 had tetanus.

Fredet,[4] at the moment of our first victory of the Marne, found in his hospital at Mary-sur-Marne 12 German wounded tended by a German medical man, who refused the antitetanic serum offered to him. Six of these wounded men died from tetanus, while Fredet, who employed serotherapy, did not see a single case of tetanus among his wounded, although they were more numerous. Many other statistics published in France demonstrate the efficacy of the preventive sero-therapy of tetanus, but only the most characteristic are here cited.

II.—*Post-seric Tetanus.*

However, the immunity conferred by the injections of serum is not absolute. As Lumière[5] says, it seems that the antitetanic serotherapy may be in default for two principal reasons:—

(*a*) When the quantity of toxin secreted at the seat of the wounds is considerable and out of proportion to the dose of serum injected. In this case the tetanus appears soon after the injection of the serum and in spite of it. Here we are dealing with an *early* post-seric tetanus.

(*b*) The immunity conferred by the preventive injection may be partly or totally exhausted at the very moment when at the site of the wounds, more or less old, cicatrised or not, tetanic sowings follow a surgical intervention or a traumatism. Either of these may liberate the spores shut up in the encysted foreign bodies. These are the *late* post-seric tetanus, and are much more frequent.

Considering the majority of the cases of tetanus observed in the present circumstances, the cases of post-seric tetanus constitute a family apart, possessing its special pathogenesis, its symptomatic picture, and, above all, its quite particular prognosis. Far from testifying to the insufficiency of the preventive serum, such cases give us, on the contrary, the most varied proofs of its efficacy. It is the presence of the antitoxin and its action which dominate the malady (Montais[6]). Everything comes down, in effect, to the struggle between the tetanic toxin and the antitoxin introduced

* The first of these Supplements appeared in THE LANCET on Sept. 21st, 1918, and comprised the following articles:—The Microbic Diversity of the Enteric Fevers, by Professor Achard; Post-Typhoid Atony of the Cæcum, by Maurice Loeper, Professor in the Faculty of Medicine and Physician to the Hospitals, Paris.

by the serum. The post-seric tetanus is more attenuated and localised in proportion as the action of the antitoxin is more powerful. It is this action of the antitoxin which regulates at once the clinical signs and the prognosis of tetanus.

The experiments of Roux and Vaillard on the preventive power of the serum are well known. Guinea-pigs are injected with a dose of filtered tetanus culture lethal to the controls in 48 hours. The animals then receive, some immediately after injection of the toxin, others at intervals of 1–6 hours, a strong dose of very active antitetanic serum. In these conditions what do we see? The tetanus will show itself earlier and more intense in proportion as the preventive injection has been made later, and the prophylactic dose of serum must then be proportionate to the delay, and must also be administered by the most rapid routes of absorption, in the guinea-pig by intraperitoneal injection in preference.

Clinically, in man the same phenomena are to be observed, and the preventive injection of serum can be seen to modify completely the clinical course of tetanus. Thus it is very difficult to fix the clinical "physiognomy" of the tetanus, and we shall not endeavour to do this. Good descriptions will be found in the book of Courtois-Suffit and Giroux,[7] and especially in the very excellent works of Montais and of Lumière already cited. One of the most striking features is the inconstancy and variability of the symptoms of post-seric tetanus (Montais, Bérard, and Lumière). In ordinary tetanus, that occurring in subjects who have never received antitetanic serum, the toxin affects successively, in a constant order, all the parts of the nervous system, from the nerves of the region wounded to the bulbo-medullary centres.

"But in the injected subjects the pathogeny is quite special; the tetanus is the result of an incomplete seric protection. In these conditions the reaction of the higher centres can, from this fact, be incomplete, irregular, and incoördinate. Instead of yielding to the toxin with the habitual regularity of the classical tetanus, each of the centres has become free to react separately, in a variable and even nconstant manner." (Montais.)

The seric injection protects in general the higher centres, which in the ordinary tetanus are the last affected. Thus many cases of post-seric tetanus are localised to the wounded limb. Courtois-Suffit and Giroux have been able to say that in these conditions the tetanus was no longer a general but a local affection. We might name it a veritable *tetanic neuritis*. Apart from those characteristic symptoms which are essentially painful cramps, this form of tetanus can give rise, like all kinds of neuritis, to trophic troubles. Bérard, Lumière, and Dunet,[8] Sencert and Cornioley,[9] have described, in the course of evolution of late localised tetanus, osteoporosis which, under the influence of the tetanic contractures, resulted in the production of spontaneous fractures.

It has been orthodox to say up to now that tetanus respected the integrity of the intelligence. And in effect the tetanic toxin, following a progressively ascending course, affected successively the peripheral nervous extremities, the medulla spinalis, and then the bulb. In this way the tetanic patients died before the brain had been affected by the tetanic toxin. But now, owing to the serum, the bulbo-medullary centres can be preserved from the fatal lesions, and the tetanic poison is seen to reach the cerebral centres and to give rise to *accidents cérébraux*. Bérard and Lumière,[10] Lumière and Astier,[11] have described these mental disorders, which consist of hallucinations, delirium, agitation, and phobias, with nocturnal exacerbation.

We would not have described all these clinical particulars if it were not possible to draw from them important elements of *prognosis*. As the seric protection, which influences the course of the malady, has only a limited duration it can be remarked in the first place, with Bérard, that—

"the longer the interval between the preventive injection and the first signs of tetanus the more the symptomatology approaches the classical form of early tetanus, and the more serious becomes the prognosis."

[7] Courtois-Suffit et Giroux: Les Formes Anomales du Tétanos, Masson, éditeur, Collection Horizon.

[11] Lumière et Astier: Société de Thérapeutique de Paris, 10 Janvier, 1917.

It can be observed further that the tetanus will be grave in proportion as the preventive injection of the serum has more or less well protected the higher nervous centres. From this point of view, as has been well shown by Montais and Lumière, great attention must be paid to the presence or absence of *trismus*. In considering this single symptom three varieties of post-seric tetanus can be distinguished:—

(*a*) *Tetanus without trismus.*—In these cases the injected antitoxin has prevented the fixation of the microbic poison on the central nervous system, limiting its action to the motor nerves of the wounded limb. These cases of tetanus without trismus are much less grave than the other forms.

(*b*) *Tetanus with late trismus.*—The bulbo-medullary centres are only incompletely protected. Then is noted the appearance of a late or incomplete trismus accompanying the local contracture. The prognosis is here less favourable.

(*c*) *Tetanus with immediate trismus* [*trismus d'emblée*].—Here the protective effect of the serum is exhausted; the route has again become free for the penetration of the toxin, and the higher centres can be affected. These cases are almost always fatal.

To compare the relative gravity of these different forms I give some very eloquent statistics from Lumière:—

Post-seric tetanus—(*a*) without trismus; (*b*) with trismus delayed or attenuated; (*c*) with trismus *d'emblée*.
(*d*) Tetanus without preventive injection.

—	(*a*)	(*b*)	(*c*)	(*d*)	Total.
Number of cases	15	13	26	27	81
Cured	11	8	8	7	34
Died from tetanus	1	3	17	19	40
,, ,, intercurrent affections	3	2	1	1	7

III.—*Therapeutic Conclusions.*

The new ideas acquired on post-seric tetanus may serve to indicate rational therapeutic action in regard to curative and preventive treatment.

A. *Curative Treatment.*

In the preface, which he has contributed to the book of Courtois-Suffit and Giroux, Widal writes:—

"In its origin tetanus is only a simple infectious localisation at the level of a wound; but, on account of the elective action of the toxin secreted by its microbe, it is as a malady of the nervous system that it presents itself to us from its first manifestations. So, to combat it, a symptomatic medication should come to the aid of the pathogenic medication. In knowing how to alleviate the crises of painful contractures the medical man gives at periods to his patient the means of passing over the dangerous stage, and can thus conduct him to the period of cellular reparations—that is to say, to cure."

The pathogenic medication is the injection of antitetanic serum. Before the war nearly everybody admitted that the antitetanic serum had no curative virtue, in spite of some suggestive observations of massive serotherapy crowned with success.[12] Roux and Vaillard, although we are indebted to them for this brilliant discovery, concluded from their experiences that—

"When the first symptoms of tetanus appear the toxin elaborated in the focus of infection has reached the nervous centres, and these may be sufficiently affected for death to occur inevitably. Injected under the skin or into the peritoneum the antitoxin neutralises, indeed, the toxin in the circulation, but does not remedy the lesions produced, and can effect nothing against a poisoning already realised."

These ideas, which were applied to the cases of tetanus habitually observed at that time—cases which arose in subjects who had received no preventive infection—are no longer true for the cases of post-seric tetanus, which during this war are much more frequent. The evolution of these latter cases is slow and retarded, and the injections of antitetanic serum in large doses seem to exercise a happy influence on this evolution. Thus on the appearance of the first symptoms of tetanus there should be injected in two or three days 100–200 c.cm. of serum and even more. It must not be forgotten, in fact, that—

"If the antitoxin can no longer act on the toxin already fixed in the nervous elements, it can still act on the toxin that the tetanus bacilli,

[12] Ch. Achard: Soc. Médic. des Hôpitaux, 9 Février, 1912. Oulmont et Dumont: Ibid., 19 Avril, 1912. J. Darier et Ch. Flandin: Ibid., Novembre, 1912.

not destroyed, can continue to pour out at the level of the wound." (Widal.)

At the present time the curative action of antitetanic serum seems indisputable.

Route.—What route should be employed? The new trials which have been made in the course of this war are, above all, based on the principle that tetanus being a nervous malady it is upon the nerves that it is necessary to act. The intracerebral route, supported by Roux and Borrel, has been almost abandoned. On the other hand, many surgeons much favour the intrarachidian route, but this seems of little practical use. Sicard has proposed paraneural injections, which are made at the junction of the limb with the trunk, and in the neighbourhood of the great nerves. Appert and Lhermitte practise epidural injection in the sacral canal, effecting thus a pararadicular injection. Walther and Jousset[13] in four cases made deep injections of serum of 20 to 30 c.cm. around the pharynx in the submaxillary region; they have thus alleviated the trismus and dysphagia. But of all the methods it seems that one alone may be practically sufficient and free from all criticism—that is the subcutaneous method.

Symptomatic medication.—But pathogenic medication, powerful though it is, has need of being completed by symptomatic medication, which is directed to the nervous phenomena; indeed, these remedies were proposed before the war. I shall not enumerate them, but will only point out two very interesting methods, due to Bérard and Lumière. These authors direct at Lyons a special tetanus treatment centre, and they have thus been able to acquire a very large experience.

Lumière,[14] having studied during several years the action of oxydising agents on the tetanic toxin, found that the alkaline persulphates possessed in the highest degree the power of destroying the tetanic poisons. He then treated the tetanic patients under his care by intravenous injections of 20 c.cm. of a pure and neutral solution (5 per cent.) of persulphate of soda, performed once or twice a day. He has obtained excellent results, which have been confirmed in particular by W. du Bouchet[15] and by Jacob. I also have been able to note the good effects of this method of medication.

Bérard and Lumière,[16] having on the other hand observed that the permanent contracture of the wounded limb is the most constant symptom of post-seric tetanus, and that this contracture, when the wound is accompanied by fracture, has the serious result of nullifying the reduction of the fracture, had the idea of combating it by *regional anæsthesia.* They have employed to this end a solution of novocaine of 1·5 per cent., with the addition of a drop of adrenalin, 1 in 1000. The injections have been made at the level of the brachial plexus for the upper limb, at the point of emergence of the sciatic for the lower limb, and in the vicinity of the nerve trunks controlling the groups of the contractured muscles. This treatment has given in all cases most encouraging results.

But it is better to prevent than to have to combat an infection so redoubtable as tetanus.

B. *Preventive Treatment.*

In order to be able to meet all the circumstances it is necessary to know alike how to prevent the early post-seric tetanus which supervenes when the prophylactic injection has not been powerful enough, and the late post-seric tetanus which appears when the prophylactic injection is too remote.

(*a*) *Prevention of early post-seric tetanus.*—Tetanus can develop soon after an injection of antitetanic serum made at the appropriate time, perhaps because there exists, together with the tetanus bacillus, paratetanus bacilli (this is a question which requires to be determined), but above all because at the level of a wound there is a superabundant secretion of toxin out of proportion to the dose of preventive serum injected. The superabundant secretion of toxin is produced especially in the freely suppurating wound, badly drained, and the first conclusion to be drawn is that one of the best ways of avoiding tetanus is to carry out early a complete surgical intervention. The second conclusion is that it is not necessary to hesitate in cases of serious wounds—above all, in the wounds of the lower limb, and quite specially in the cold-bites of the feet which have led during this war to such a large number of cases of tetanus—to make at once an injection of 20 or even 30 c.cm. of antitetanic serum. Repetition of the injection of serum is indicated every eight days for one month after receipt of the wound when dealing with infected wounds. This wise prophylactic measure is, however, insufficient. The immunity persisting for only about 15 days after the last injection of serum, it results from this that at the end of 45 days the patients are no longer protected by the previous inoculations. Now, tetanus has often been observed to appear more than 50 days after the wound. How are these late cases of tetanus to be prevented?

(*b*) *Prevention of late post-seric tetanus.*—The late post-seric tetanus supervenes after a delay of from one month to four months, and even more, after the wound—for example, 212 days in a case of Bérard and Lumière. To what are these cases of late tetanus due? In wounds which cicatrise slowly and are infected the spores of tetanus remain in a latent state as long as they are bathed by organic fluids containing the antitoxin of the serum. But when this last is exhausted by lapse of time microbic vegetation can take place and tetanus appears. In the cicatrised wounds the spores of tetanus can exist on the surface of projectiles. Bérard and Lumière have found them in three cases out of four.[17] They can also be found in the depth of old cicatrices, or even at times may come from the intestine of the wounded men. Any traumatism, and more particularly a surgical traumatism, operation, massage, mobilisation, suffices to set free the infection.

From this comes the rule laid down by Pierre Bazy, Bérard and Lumière, and a large number of French surgeons: always to practise a fresh injection of serum at the moment of the complementary surgical intervention which may liberate the infecting germs. However, this mode of action is not always sufficient. In certain wounds, which have a slow evolution or still contain foreign bodies, it can be observed that the tetanus constitutes a *permanent menace.* The question arises whether by means of injections of serum this permanent menace can be met. We have answered this question, M. Vallée and myself, in proposing *antitetanic vaccination.*[18] It is not logical, in fact, to seek to obtain durable effects from the serum, the action of which is always ephemeral. If it is desired to put rapidly, though for a short period, the wounded men in safety from tetanus it is necessary to supply them with the antibodies, already formed and immediately utilisable, that the serum represents. If, on the contrary, a prolonged menace of tetanus is feared the medical man can protect his patients by the slow but durable action of a vaccine.

Inspired by the work of Roux and Vaillard, we have employed as vaccine an iodised toxin, the same as is used at the Institut Pasteur to prepare the horses providing serum. The power of the toxin which we have employed is such that 1/10,000 c.cm. sufficed to kill a guinea-pig of 400 g. On mixing this toxin with an iodised solution (iodine 1 g., iodide of potassium 2 g., distilled water 200 g.), in the proportion of two-thirds of toxin to one-third of iodised solution, there is obtained a liquid neutral for the organism, but yet capable of vaccinating it. At first—acting, as can well be supposed, with the greatest prudence—we injected the wounded men a first time with 1 c.cm. of this iodised toxin, a second time with 2 c.cm., and a third time with 5 c.cm. of toxin mixed with 2 c.cm. of iodised solution. Since then we have much increased the doses. There can easily be injected the first time 4 c.cm. of iodised toxin, the second time 8 c.cm., and the third time 12 c.cm. It is possible to increase further the number and dose of the vaccinal injections, which are remarkably well borne and provoke neither local nor general phenomena.

We shall pursue, M. Vallée and myself, further researches on this antitetanic vaccination. Up to the present the results which it has given us are so satisfactory that we can recommend it to our British friends in the hope that it will render them service. With the serum and with the vaccination it seems that we are now better armed against tetanus, and I desire to reproduce the conclusions that I stated at the

Société de Chirurgie in June, 1917, so as to define precisely the indications of the two methods.

"Immediately after the wound practise without delay an injection of antitetanic serum, which you will repeat in case of need at intervals of some days, so as to guard against immediate accidents. Then, favoured by the immunity thus conferred on the wounded man, it will be legitimate treatment to render his resistance tenacious by submitting him to vaccination. It is recommended that this be carried out only five days at the soonest after the last seric injection, so as to avoid part of the toxin being absorbed by the antitoxin of the serum and thus becoming unsuitable to ensure the immunising reaction."

Such are the new ideas that the war has brought forth on tetanus.

TETANUS CONSECUTIVE TO SUPERFICIAL WOUNDS AND TO TRENCH FOOT:

TREATMENT AND PREVENTION.

BY PROFESSOR RAYMOND,

MÉDECIN PRINCIPAL DE 2e CLASSE.

I SHALL confine myself in this short note to giving the result of my personal clinical experience on the two following particular points: (1) Treatment of tetanus consecutive to superficial wounds; and (2) tetanus in trench foot.

Treatment of Tetanus Following Superficial Wounds.

I have watched two cases of tetanus consecutive to superficial wounds.

1. The first case was that of a soldier who had a slight wound in the region of the back caused by a small piece of shell. The wound was so slight that the man did not seek treatment, but some days later presented himself because of trismus. On admission to hospital he presented a typical tetanus with generalised contractures, trismus, dysphagia, convulsive crises, elevated temperature, &c. The treatment consisted of: (1) Excision of the little wound as done for malignant tumour; a small metal fragment was found in the excised tissues. (2) Serotherapy in large doses; 100 c.cm. of serum each day injected hypodermically; this treatment was continued for a fortnight. Gradually the crises became less frequent, the trismus, the dysphagia, and the contractures subsided. Towards the tenth day, as there was remission of temperature and the urine contained a large quantity of albumin, it was decided to discontinue the injection of serum. Immediately the temperature rose again, with aggravation of the symptoms. The seric treatment was again resorted to, whereupon the temperature fell, the symptoms disappeared, and cure became definite without fresh incident or complication.

2. The second case is analogous. A soldier received a very slight wound of the face in the region of the inferior maxilla. At first he did not seek treatment, but was obliged to do so, some days after his wound, for facial paralysis. He entered hospital with this diagnosis. A careful examination revealed slight crises of trismus on percussion of the inferior maxilla. Some hours later the complete symptomatology of tetanus appeared. The treatment consisted, as in the first case, of excision of the small wound, carried out as for a tumour, and intensive serotherapy. To start with, some intra-rachidian injections were made, but subcutaneous injection in doses of 100 c.cm. each day constituted the basis of the treatment. The affection evolved as a grave form; there were very disquieting bulbar and cerebral symptoms. Then by degrees cure took place. The only accident was an eschar of the thigh consecutive to the injections of the serum.

In these two cases we are dealing with a tetanus consecutive to a very superficial wound, so superficial that the wounded man did not present himself for treatment, and consequently did not receive preventive injection of antitetanic serum. The treatment has been based on:—

1. Excision of the wound. This was carried out as in the case of a malignant tumour, by circumscribing very widely the whole region of the wound. The object was to remove the tetanigenic germs with the tissues which contained them, without causing the penetration, by way of the operation wound, of tetanic toxin into the circulation. The excision has had in these cases, in our opinion, a preponderant action by the suppression of the focus of permanent production of poison.

2. The excision of the wound having suppressed all new access of tetanic toxin, it only remained to combat the toxin already fixed in the tissues. Here serotherapy in high doses has given excellent results. In the first case in particular its efficacy has been shown; on stopping the therapy a disquieting recrudescence of the symptoms immediately followed. The doses employed have been 100 c.cm. of serum each day by the subcutaneous route. The injections have been continued until the infection was overcome—that is to say, from 10 to 15 days. We have employed French or American serum; in the former the dosage is based on the cubic centimetre, and in the latter on the antitoxic unit. 10 c.cm. of French serum of the Institut Pasteur correspond to 1500 antitoxic units of American serum.

Tetanus in Trench Foot.

The affection called "trench foot" or "*gelure* of the feet" is very often accompanied by tetanus. This fact has been recorded by former authors, at the time of the wars of the First Empire and of the Crimea, but it has been lost sight of, so that the appearance of tetanus in trench foot has been a veritable surprise in the present war. Since our first studies with Parisot we have recorded the frequency and the gravity of this complication. We have observed especially two cases in the following conditions.

We had under treatment in our service 50 native soldiers, admitted the same day for a grave form of trench foot, with massive œdema of the legs, very extensive eschars, and profound infection of the tissues. To these local symptoms were joined an elevated temperature and the signs of general septicæmia that we find associated with this malady. All the patients had received a prophylactic injection of 10 c.cm. of antitetanic serum.

On the eleventh day one of the patients presented acute symptoms of tetanus and died in 36 hours. We administered at once a fresh injection of 10 c.cm. of antitetanic serum to all the patients, but this did not prevent another man having tetanus as grave and rapid as the preceding and leading to death in 48 hours. We then made an injection of 30 c.cm. of antitetanic serum in all the other patients, and we had no further cases of tetanus.

Numerous observers have recorded analogous facts, so that it can be said that trench foot is, above all, the tetanigenic affection, more so even than the wounds in war. This is very easily understood if we think of all the contaminations which are found on the feet of those who have stayed in the dirty water of the trenches, of the diminution of resistance of the tissues brought about by this stagnation, and, finally, of the microbic flora that have been described in this affection.

Tetanus in trench foot is always grave, and almost all the cases have been fatal. If now, in accordance with what has always been our view—a view supported by numerous authors—the medical man avoids systematic amputation of the feet, it is of importance, so as to guard against the formidable complication of tetanus, to comply with the following rules: 1. To make in all cases a prophylactic injection, as early as possible, of 20 c.cm. of antitetanic serum. 2. To repeat this injection, in all the cases where there has been loss of substance of the integuments, phlyctenæ or eschar, at the end of eight days. 3. Not to fear, in the grave forms with extensive gangrene, infective manifestations, to increase the doses and inject 30 c.cm. and more. 4. To make an injection of 10 c.cm. at the least every eight days as long as there exist sphacelated tissues, necrosed or suppurating zones—in short, as long as the wound is not in the way of definite cicatrisation. 5. It is well not to allow an interval of more than eight days between each injection of antitetanic serum, alike to assure the continuity of the antitoxic treatment and to avoid seric or anaphylactic accidents.

Thanks to this practice we have had, Parisot and myself, only the two cases of tetanus just related among several hundred serious cases treated in our centre.

LONDON: SATURDAY, OCTOBER 19, 1918.

Pratt and Others v. The British Medical Association.

IN the King's Bench Division during the last fortnight of July there was heard at great length before Mr. Justice MCCARDIE an action by Dr. ERNEST CAMDEN PRATT, Dr. DAVID HOLMES, Dr. ANDREW ST. LAWRANCE-BURKE, and Dr. CHARLES HODGES CAIRNS (deceased) against the British Medical Association and certain members of the Coventry Division of the British Medical Association. The plaintiffs, who were at the time of the institution of the action medical officers of the Coventry Provident Dispensary, claimed damages for conspiracy and injury in their profession and for libel and slander. The opening addresses of counsel, both for plaintiffs and defendants, as well as the more pertinent evidence tendered on each side, were published in the medico-legal columns of the *British Medical Journal* on August 3rd and 17th, and, abbreviated although these reports are, the complicated arguments employed emerge well from them. In fact, this report was a remarkably accurate account of the principal features of the case. The exact definitions, and the legal and popular meaning attached to such terms as "conspiracy," "malice," and "professional honour," were debated; the fundamental divisions between free hospitals (taken as the type of completely philanthropic institutions) and provident dispensaries (where the work is not of a purely charitable nature) came under discussion; the powers and scope of the British Medical Association as opposed to those of a trade union were seen to be in question; the methods in which those powers were employed were described; and no one was surprised on the last day of the protracted hearing when Mr. Justice MCCARDIE, who had throughout displayed the greatest anxiety to make a complicated story clear, reserved his judgment in view of the legal importance of the case. With the consent of the plaintiffs the judge was sitting without a jury, and he explained frankly that he felt the onus upon him very heavy, inasmuch as not only the individual rights of persons alleged to have suffered were at issue, but questions of the first moment to the medical profession and the community.

Mr. Justice MCCARDIE delivered his lengthy judgment on Tuesday last, concluding with a verdict on the principal counts for the plaintiffs. Our readers are probably familiar with the main facts of the story, which is far too long a one to be treated in any categorical manner, although his lordship, in the course of his judgment, gave a very effective résumé of the salient facts. For very many years the conduct of the Coventry Provident Dispensary was considered unsatisfactory by the local medical men. The professional point of view was set out in articles which appeared in our columns, and which took note of the ancient history, but for the purposes of the case, as decided against the British Medical Association, it is not necessary to go further back than 1906. This year marked the high level of the success of the Dispensary, and in this year the opposition of the Association took formal shape, when the following three causes of complaint against the institution were formulated: That the canvassing of the public for patients through a collector, paid on commission, was professionally improper; that the management was too exclusively in lay hands; and that no proper wage limit was imposed upon the subscribers for medical aid, and that such limit was not retrospective. The result was a conference between the local medical profession and the managers of the Dispensary, when the first medical point was conceded, a salaried collector being substituted for one paid on commission; but no change of constitution was considered in respect of the other two points. Thereupon five of the medical staff of the Coventry Dispensary resigned, and in 1907 a medical club was started under medical auspices, the British Medical Association deciding that members of the Association ought not to take medical office at the Dispensary. Had the Association been able to prevent the Dispensary from obtaining medical service, at any rate until its house was set entirely in order, contract practice in Coventry would have taken the shape which most of the profession who had thought upon the matter considered to be best both in the public and professional interest; but the Dispensary was able to find medical officers, despite the representations of the Association. Whereupon the Coventry Division of the British Medical Association, supported by their central organisation, proceeded to make things professionally disagreeable for practitioners who held office at the Dispensary. Members of the Association were forbidden to enter into professional relations with the medical officers of the Dispensary, either in ordinary or consultant capacity, and the ostracism was extended, as far as might be, to practitioners who were not members of the Association. The action of the four plaintiffs against the British Medical Association as an organisation, and against certain local members of the Association, arose out of the situation in which they found themselves as medical officers to the Coventry Dispensary while under professional boycott. The legal proceedings commenced long ago, and one of the plaintiffs is dead; nor were the other three in wholly comparable situations in bringing their joint action, but substantially their grounds of complaint were identical. In the main, what Mr. Justice MCCARDIE had to determine was whether the ostracism of the medical officers of the Coventry Provident Dispensary, admitted by the defendants, was lawful.

Mr. Justice MCCARDIE found for the plaintiffs on all counts, holding the coercive action of the British Medical Association illegal. He alluded to the disciplinary measures of the Association as an improper assumption of power; and by describing the penal

powers of the General Medical Council with detailed accuracy he intended, we must suppose, to suggest that those powers are sufficient to meet all cases of improper medical conduct so far as the public is affected. In the awarding of damages he laid stress upon the blameless professional conduct of the plaintiffs, and was influenced by his reluctant conclusion that malice had played a part in the attitude of the Association towards them. He held that the Association, to whose good work and high position he more than occasionally paid tribute, had been, in many of the circumstances under consideration, impelled by mixed motives—partly by a real desire to uphold the honour and interests of the medical profession, but partly by an intention to punish defaulters from the standards erected by the Association. Mr. Justice MCCARDIE'S verdict had been very generally anticipated.

Wounds of Joints.

DURING the four years of the grim struggle now drawing to its close, in which the human body has been the principal target, joints have been wounded by rifle- or shell-fire in about 1 in 25 of the direct hits recorded. Presumably the joints occupy about this proportion of the whole exposed surface of the body. Surgeons have, in consequence, gained a large experience of the various methods of dealing with joint wounds, and initial wide differences of opinion are now giving place to a remarkable degree of agreement on the general principles of treatment. We have already published a number of articles on the subject and are glad to include in our present issue the second part of a paper by Captain J. CAMPBELL, which gives a useful summary of these principles. It is not long since joint injuries were regarded with something like dismay. Grave indeed they are, but we have learned that articular surfaces have no small power of self-protection, which does much to prevent and to limit the evil effects even of the severest injuries and infections. Synovial membrane may be trusted to overcome bacterial invasion, when not of overpowering virulence, provided that exit is afforded to the exudate which the membrane pours forth. Moreover, in the face of any agent causing inflammation the synovial membrane readily forms adhesions, and so rapidly are these produced that, in the course of a few hours, openings through which sepsis might enter are completely shut off, while sepsis which has already invaded the joint is localised within narrow limits. The properties of the tissues forming the articular ends of the bones have also important bearings. Articular cartilage is avascular, yet it does not readily undergo erosion even in the presence of sepsis unless subjected at the same time to pressure. When pressure is exerted sepsis leads rapidly to erosion. Hence, so long as sepsis is present in a joint it is logical to prevent pressure on the articular cartilage by the judicious use of extension. The bone underlying the articular cartilage receives no vessels from the articular surface, with the result that if any portion has its lateral blood-supply cut off, this portion of bone must die, forming a sequestrum which will then greatly facilitate the spread of any sepsis present. These are some of the fundamental considerations on the application of which depends the successful treatment of joint wounds.

Other points for deliberation have reference to time and circumstance. It is clear that when cases of joint injury are seen early an immediate operation is indicated provided that the patient is in a condition to stand the shock. The operation would then consist in the removal of any foreign body present and of any loose portions of bone, the excision of the wound, and its complete closure. In a large proportion of the cases so treated the result leaves nothing to be wished. If, on the other hand, a period of 24 or 48 hours has elapsed since the injury was inflicted, and if the joint meanwhile has been well immobilised and efficient extension applied, there can be no object in interfering, while all appears to be going well. Information obtained by X ray examination may now be of great value in deciding what shall be done or left undone, and the report on the character of invading organisms will also have its influence on the choice of treatment. The general principles for conservative treatment have already been indicated by anatomical considerations. First and foremost, the joint must be kept absolutely fixed, for movement diminishes relatively the chances of recovery; at the same time, the articular surfaces must be prevented by suitable extension from rubbing together. The number of splints introduced for this purpose during the war is legion, many of them both simple and ingenious, but the fact remains that for either limb some modification of Thomas's original knee-splint appears to serve every purpose. Several patterns of this splint are now made which allow of an easy application of extension, and practical experience has already shown their efficiency. In regard to operative procedures, excision of the joint should be reserved for early cases where the ends of the bones are much injured, but where a prospect remains for obtaining either a strong and fixed joint, or one in which some movement is retained; the amount of bone removed will vary accordingly. In late cases benefit will rarely be derived from excision, for severe sepsis adds a great danger to carrying it out. Many cases unfortunately still remain in which the injury is too severe, or the strength of the patient is too much impaired to allow of any conservative measure whatsoever, and in these amputation provides the final alternative.

Debatable points of technique there still are. The use of antiseptics in the joint is questioned by some, although many who have had experience with Professor RUTHERFORD MORISON'S bismuth and iodoform paste speak in the highest terms of its value. In early cases it certainly does marvels, but its employment when sepsis is well established is more doubtful. Captain CAMPBELL has something to say regarding the quantity employed, which should not be sufficient to constitute in itself a foreign body. In septic cases CARREL'S method has its special value, and the employment of irrigating tubes may enable secondary suture of

the wound to be performed later. Much depends on which is the actual joint involved. In respect of response to treatment no two joints are alike. In a large joint, such as the knee, drainage by lateral incisions is of little value; and where drainage has to be employed at all, openings should be made through the posterior wall of the joint. In the hip, the presence of the head of the femur, cut off from its blood-supply and surrounded by sepsis, is a definite hindrance to recovery, and in the opinion of many excision is imperative. While so much is firmly established, much still remains to be learned about the treatment of gunshot wounds of joints, but what has already been learned will be applied to the various injuries of civil life, with a vast improvement of joint surgery.

Annotations.

"Ne quid nimis."

THE CHANGES IN UNIFORM AND TITLES IN THE MEDICAL BRANCH OF THE NAVY.

THESE changes, recently introduced, may be of a far-reaching character; they must be regarded as almost revolutionary in such a conservative service as the Navy. Therefore all the more credit is due to the present Board of the Admiralty for broad-mindedness in facing the problem of making public the conviction that all the different branches of the Navy are limbs of the same grand tree. The changes are a timely recognition on the part of the Admiralty that in a modern man-o'-war the hazards are shared by all, and the casualty lists leave no doubt that the medical personnel has borne its full share of recent perils. Up till now the uniform of officers in the Royal Navy has been of two types—viz., that worn by the executive and engineers, and that by the other branches, including the medical service, the paymasters, and naval instructors. The former was distinguished by a curl surmounting the upper ring of gold lace on the cuff and by oak leaves instead of a plain gold band on the cap. All now wear the same uniform. The coloured cloth (red in the case of the medical officers) between the gold stripes will persist, and is so distinctive that none but the colour-blind can fail to recognise at a glance the officers of the medical service. Where two different types of uniform were worn by officers belonging to the same service invidious comparisons were bound to exist. The changes should result in a closer union between all the different branches of the service, where uniform means so much. The new titles are of a compound nature, and comparing them with the old we have—

Old.	*New.*
Surgeon Probationer, R.N.V.R.	Surgeon Sub-Lieutenant, R.N.V.R.
Surgeon.	Surgeon Lieutenant.
Staff Surgeon.	Surgeon Lieutenant Commander.
Fleet Surgeon.	Surgeon Commander.
Deputy Surgeon-General.	Surgeon Captain.
Surgeon-General.	Surgeon Rear-Admiral.

We are not much in favour of compound titles, but we recognise the good intentions underlying the change. There are other questions in the Naval Medical Service which require attention, but the changes in uniform and titles are an earnest of intended procedure which should influence young doctors in looking to the Navy for a future career.

UNIVERSAL ANÆSTHESIA.

THE remarkable case described in another column by Captain E. D. Roberts, R.A.M.C., offers a problem in diagnosis to the neurologist, apart from its intrinsic interest for all who find attraction in the by-paths of medical lore. The patient is a Breton sailor, aged 37, who apparently shows no signs of disease, organic or functional, in his nervous system, except in regard to his sensory apparatus. His condition is one of universal anæsthesia, cutaneous and deep, involving all varieties of the former and some (not all) of the special senses. For the actual details the reader is referred to Captain Roberts's painstaking description. There are certain features of the case which have struck the reporter as somewhat anomalous, and which are worth a little investigation. The patient is unable to make any voluntary movement with the arms when the eyes are closed; without visual control he cannot innervate with accuracy. Oddly enough, though muscular sense is apparently as defective in the legs as in the arms, he can walk quite well with the eyes shut, and he can swim, in spite of the fact that in that art the limbs are not under visual control. This is the condition described by Nothnagel in 1887 as *Seelenlähmung* of organic origin; in certain lesions of the parietal cortex loss of kinæsthetic images of the range and form of voluntary movements occurs, with consequent inability to innervate accurately. Where there is not merely loss of kinæsthetic images, but also loss of appreciation of kinæsthetic impressions, the patient has to depend on his visual memories and impressions of movements, and is helpless without them. Now in the present instance there is no evidence of a parietal lesion, nor, as already noted, is the *Seelenlähmung* constant or logical in its manifestations—a strong presumption in favour of the hysterical nature of the case. Again, when the eyes are closed the limbs may be passively put in any position, and they are so maintained by the patient—a condition of flexibilitas cerea. The mere fact of the position being sustained is proof of the innervation of the muscles in consonance with the kinæsthetic impressions awakened by the passive movement made by the observer. Hence these impressions are certainly present, though the patient may not be actually conscious of them—a point which again pleads in favour of the diagnosis of hysteria, and can scarcely occur in organic loss of kinæsthetic impressions as in advanced syringomyelia. The curious pica shown on occasion by the patient is worth notice, for it is not, of course, in any sense an indication of organic disease. The extraordinary thermanæsthesia is, no doubt, such as may be found in severe cases of syringomyelia. We are reminded of the "professional painless man" whose case was described by Witmer in 1897. In this case the patient could hold a red-hot half-dollar in his hand without wincing until it had burned itself deep into the flesh. Witmer came to the conclusion that the subject did not perceive the pain, and not that he was stoically enduring it, and concluded he possibly suffered from syringomyelia. But the facts of hysteria mutilans show that similarly profound anæsthesia for all stimuli may occur in that psychoneurosis, and we are inclined to suggest to Captain Roberts that hysteria by itself, as readily as the combination of hysteria and syringomyelia which he himself puts forward, will account for the symptomatology of this curious case. The profession is indebted to Captain Roberts for putting the case on record.

MEASURES AGAINST INFLUENZA IN GLASGOW.

THE great industrial city of North Britain has had its public life much interfered with by the serious outbreak of influenza. In the third September week school children in the Shettleston area attended very irregularly, and influenza soon invaded the schools in Govanhill, and then generally throughout the city; incidentally the general death-rate rose from 13·5 to 18·6 and 28·6 in the last week of September and the first week of October. This last-named figure is without precedent since 1909, when an equally high death-rate was associated with intense frost and fog. In the three weeks under review the total deaths registered were 257, 374, and 549, of which 16, 65, and 165 were credited to influenza, 30, 65, and 107 to pneumonia, leaving only 66 to the other forms of respiratory disease. In the same period measles, scarlatina, whooping-cough, and diphtheria together only claimed 29 victims. The dislocation of school attendance was not due to any special incidence at school age, although the proportion of deaths at ages under 5 years was strikingly in excess, as is shown by the following table:—

Age.	Proportion of population.	Proportion of total deaths for the week ending—	
		Sept. 28th.	Oct. 5th.
0–5 years	11·6 per cent.	20 per cent.	24 per cent.
5–15 ,, ...	20·8 ,,	20 ,,	19 ,,
15 years and upwards	67·6 ,,	60 ,,	57 ,,

The decrease in school attendance has been fairly uniform throughout all the standards, and is thus in striking contrast with the effect of an outbreak of measles, which is chiefly noted in the infant classes. This general prevalence raised some doubt as to the utility of school closure, but acting on the view that the risk of infection is always intensified when susceptible persons are collected together under one roof, Dr. A. K. Chalmers, the medical officer of health, adopted experimental closure of certain schools where absenteeism was at its maximum. Nine other schools have now been closed. With regard to the method of spread, everything points to aerial conveyance. There was nothing to suggest direct spray infection, but rather the access of organisms to the body by the nasal passages. Nurses in contact with the disease readily contracted it. Special preventive measures should therefore, in Dr. Chalmers's view, aim at intercepting the organism during the act of breathing by some agent supplied to the nasal passages and air cavities. He quotes Dr. J. Macintyre's suggestions for applying germicidal substances to the nostrils:—

"If the vehicle in which it is used is the proper kind a very few drops on a handkerchief will act for 12 to 24 hours, or every now and then the agent can be inhaled into the nostrils, and, of course, if the air be taken in through the nostrils this volatile substance will be carried right down to the apices of the lungs. This method of treatment does not mean that sprays or douches should not be used, but what I have found is that for diseases of the respiratory tract, by means of some of these agents and methods of administration, a great deal can be done by way of sedative and antiseptic means to relieve the patient from suffering, and to enable the whole respiratory tract to be kept in a healthy condition."

Dr. Chalmers adds that there seems reason to expect advantage from these measures when exposure to exceptional risk is encountered, as in public assemblies, picture-houses, and conveyances. He considers it essential at the same time not to neglect any factor contributing to personal hygiene.

MENINGOCOCCIC PURPURA WITHOUT MENINGITIS.

AT a meeting of the Société Médicale des Hôpitaux of Paris, M. Arnold Netter and M. Marius Mozer reported the case of a malê infant, brought up on the bottle, who was taken to the Trousseau Hospital at 9 A.M. on July 17th. He had been ill for ten days with diarrhœa and tympanites. On the 15th an eruption appeared the nature of which could not be determined at the Saint Louis Hospital. On examination the child was wasted and the eyes were sunken. On the face, trunk, and limbs were numerous little violaceous spots of equal size which did not disappear on pressure. They were evidently purpuric. The temperature was 101·8° F., and there were no signs of visceral disease, no stiffness or Kernig's sign, and the fontanelle was rather depressed. Lumbar puncture yielded clear liquid, not under much pressure, which on centrifugalisation gave a fine deposit containing extracellular diplococci not retaining Gram's stain, and having all the appearances of meningococci, and a few lymphocytes. There were 42 mononuclears to the c.mm. The purpura, therefore, appeared to be due to meningococcic septicæmia, and invasion of the meninges seemed to be imminent. Twenty c.cm. of polyvalent antimeningococcic serum were injected into the sacro-lumbar muscles at once, and the dose was repeated at 6 P.M. Cultures were made from the cerebro-spinal fluid and from blood removed from the jugular vein. The child died at 6 A.M. on the 18th. Four hours after death cerebro-spinal fluid was removed from the lumbar region of the cord and from the right lateral ventricle. The fluid was not yet purulent, but was not so clear as that removed on the previous evening. It contained numerous meningococci, principally extracellular, and cells, amongst which were numerous polynuclears. The blood and the fluid from the lateral ventricle gave pure cultures of the meningococcus, but the cerebro-spinal fluid removed during life gave no culture. At the necropsy the viscera were found normal, with no hæmorrhages. The brain showed only some injection. Without the microscopic examination the localisation of the meningococci in the meninges could not have been recognised or the nature of the disease suspected. M. Netter had recourse to lumbar puncture because he had long observed the relations of meningococcic infection with purpura and had found meningococci in the lesions of purpura. In such purpuras it is not exceptional to obtain cerebro-spinal fluid of normal appearance, which may even contain no microbes. Invasion of the cerebro-spinal fluid occurs after the infection and first in the cranial cavity. In the present case the septicæmia preceded the meningitis.

ACCURATE CLINICAL THERMOMETRY.

THE importance of a correctly recording clinical thermometer receives official recognition in an Order issued last week from the Ministry of Munitions of War. This Order demands that on and after Oct. 21st, 1918, no person shall sell, offer for sale, supply or deliver, any clinical thermometer which has not been tested, approved, and marked in accordance with rules made by the Controller of Glassware Supply on behalf of the Minister of Munitions in consultation with the Local Government Board and the Department of Scientific and Industrial Research. Clinical thermometers must in future bear the stamp of approval of the National

Physical Laboratory, Teddington, and this approval will not be given in regard to thermometers, after a period of one month after the date of the Order, which show at any point in the registration of temperatures an error of more than 0·4° F (+ or −, we may presume). The approved thermometer will be marked with the National Physical Laboratory trade-mark and the year of test, thus—NP 18. Nominal charges are made for the test and guarantee. This Order will bring pressure upon the work of the National Physical Laboratory, which has already undertaken such standardisation voluntarily and in return for a fee, and there are good reasons, doubtless, for making such a step compulsory. Medical men as a matter of scientific routine take care in their work of diagnosis to use correctly recording instruments, but the clinical thermometer has become almost a family guide, and the periodical taking of temperatures is often left in lay hands. To read accurately a thermometer which may prove to be inaccurate in its readings is to mislead the physician. The Order of the Ministry of Munitions brings into prominence the position of the National Physical Laboratory as a centre of standardisation of physical instruments.

SIR WILLIAM HENRY THOMPSON.

ONE of our Irish correspondents calls attention to the presumed loss on the *Leinster* of three members of the medical profession, one of whom was William Henry Thompson, M.D., K.B.E., whose name is closely associated with the scientific aspect of food values. Post-graduate study at Galway, Dublin, London, Leipzig, Paris, Marburg, and Heidelberg widened his outlook, and as King's Professor of Institutes of Medicine in the School of Physic at Trinity College, Dublin, he had long made food metabolism and nutrition his special study. Early in 1916 he read a paper before the Royal Academy of Medicine in Ireland giving a detailed survey of the food-supply of Great Britain on the lines of the Eltzbacher report brought out in Germany 12 months earlier. His intimate acquaintance with food economy, both large and small, made him a valued member of the Advisory Committee to the Ministry of Food, where he placed his knowledge unreservedly at the disposal of other medical colleagues through the columns of THE LANCET whenever his official position allowed of the publicity. One great merit lay in his ability to reduce the cold details of calories and energy values to terms of interest for the common man's breakfast-table. His article in a recent number of *Science Progress* was a conspicuous example of this facility.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A quarterly meeting of the Council was held on Oct. 10th, Sir George Makins, the President, being in the chair. The President reported that on August 14th the Right Honourable Sir Robert Borden, G.C.M.G., the Canadian Premier, accompanied by officers of the Canadian Army Medical Corps, visited the Museum and formally opened the Canadian Section of the War Office Exhibition of Medical Specimens. The Library Committee reported that Mr. Plarr, the librarian, was preparing a Roll of the Fellows, for which he has written about 1410 lives up to the present time. The Council, in pursuance of the recommendation of the Jenks Scholarship Committee, appointed Mr. Thomas Haines Sims, late of Epsom College, the twenty-sixth Jenks Scholar. The Council, in response to a letter from the Medical Secretary of the British Medical Association, approved of the calling of a conference in regard to the establishment of a Ministry of Health. The President reported that the Bradshaw lecture on "Cancer of the Tongue" would be delivered by Mr. D'Arcy Power on Thursday, Nov. 14th, at 5 P.M.

THE MEDICAL MAN'S INCOME-TAX.

BY JOHN BURNS, W.S.

PAPER restrictions compel what follows to be a study in income-tax and condensation combined. This article, also, does not deal with super-tax.

Income.—Ordinary professional income is taken on the average of the preceding three years. The income from specific appointments under public bodies is taken on the actual amount of the year. The former is charged under Schedule D, the latter under Schedule E. Where appointments carry not only a salary but also free residence, board, service, &c., only the cash salary is taxable income; the other items do not count at all. Sums received for drugs must go in as drawings. But, of course, what is taxed is net income, and therefore many deductions must come off. These include: rent or annual value of premises used exclusively for practice; a proper proportion of rent or annual value of residence, according to the part used for practice, not exceeding two-thirds; rent or annual value of garage or stable; inhabited house duty and tenants' rates, heating and lighting, corresponding to the above items; assistants and locum tenens; service applicable to the professional practice, including maid servant and secretary or book-keeper and any assistance obtained in dealing with the income-tax problem; travelling, including railway, car, carriage, and for horses, not the original cost, but all running expenses, repairs, and renewals, less salvage for the old articles; instruments, with the like restriction; drugs, &c.; professional subscriptions and literature; telephone, telegrams, stationery, and postage. As regards practice (except appointments), an account is made upon these lines for, say, each of the three years, April, 1915, to April, 1916, also 1916–17, also 1917–18, and adding the net results together and dividing by three there is brought out the "statutory income" under Schedule D tax for the now current year, April, 1918, to April, 1919. To that will be added the cash salaries of any public appointments for that year.

Cash or earnings.—There is an option to deal with the drawings on the basis of either cash or earnings. The cash system means that you ignore all fees earned but not actually received, and all expenses incurred but not actually paid. Of course, these will all come in next year or later. This saves you all trouble about bad or doubtful debts. The earnings system, on the other hand, brings into account everything earned or incurred respectively, though not received or paid; but, of course, the same items must not figure more than once. If under this system you estimated fees due to you £20, and if you receive only £15 or £25, only the difference of £5 will be treated in next year's account. We believe that nearly all practitioners adopt the cash system.

Actual income.—If you are serving in the R.A.M.C., or doing other war work as explained below, you are entitled to throw over the three years' average and to be assessed on your whole professional practice at the actual figure of the year. That can be ascertained only at the end of the year, and there will then be an adjustment. This holds whether you adopt "cash" or "earnings." Actual cash is treated as actual income. Further, in any case, war work or not, if your actual income of the year from all sources, taken together (including wife's), is less by more than 10 per cent. than the total charge made on you by direct assessment and deductions, then you are entitled to claim to be taxed on the actual income only.

Other income.—Of course all your non-professional income must be added on in order to reach your total, and so to fix your rates of tax and abatements, if any. This includes income from investments, and the annual value of your residence if it belongs to you or to your wife, but only at the net Schedule A assessment figure.

Wife's income.—This reminds us that your wife's income must for tax purposes be added on to your own. There is an exception of her separately *earned* income, if the total of both does not exceed £500.

Deductions.—You take off all true deductions—e.g., ground burdens, mortgage interest, bank interest, interest on price of practice.

Rates of tax.—Broadly, these are the items which make up the total. That total fixes your rate or rates. You may or may not be entitled to abatements (below), but these do not affect the *rate* or *rates*, though they do affect the sum on which these are payable. The rates are:—

If total income does not exceed—	Rate of tax on the part which is—		
	Unearned	Professional.	War work
£	s. d.	s. d.	s. d.
500	3 0	2 3	1 3
1000	3 9	3 0	1 9
1500	4 6	3 9	2 3
2000	5 3	4 6	2 9
2500	6 0	5 3	3 3
Over 2500	6 0	6 0	3 6

Abatements.—These are the rates, but on what are they payable? Answer: The net total above indicated, less abatements, as follows:—

1. *Scale.*—If total not over £400, £120; if not over £600, £100; if not over £700, £70.
2. *Wife.*—£25 if total income not over £800.
3. *Widower's housekeeper.*—The same. The housekeeper must be a relative of the taxpayer or of his late wife, and there must be a child under 16.
4. *Children.*—£25 for each child, step-child, or adopted child under 16. If the income does not exceed £800 all such children count; if it exceeds £800, but is not over £1000, all under 16 count bar two; if over £1000, no allowance.
5. *Life insurance.*—Premiums up to one-sixth of the taxable income. Suppose income £600, and the abatements £200, still this insurance abatement may be £100 if so much has been paid. There are certain restrictions, especially upon new policies effected after June, 1916, and, on the other hand, war "extras" are allowed beyond the one-sixth. Also it may be one-sixth of the 1913-14 (last pre-war) income, if that was larger.
6. *Incapacitated dependent relatives.*—If total income not over £800, £25 for each such relative of self or wife maintained by you, if relative's income not over £25.
7. *Marginal.*—In applying these scales and income limits there is come and go to this extent that if you are, say, £5 above some limit you pay that £5 to the Commissioners and then you get off as if you had never had it. If your income is, say, £810 and you have a wife and a lot of young children this is valuable.
8. *Officer's uniform.*—There is an allowance (of varying amount) for this if you are an R.A.M.C. or other officer. It is treated as an actual deduction from the pay, and not merely an abatement. It may alter the whole position.

Applying the abatements.—They always come off the lowest taxed part of your income first. This may greatly lessen their value. If you make £600 and your wife has from investments £200 all abatements will be first taken off at the 3*s.* rate and not at the 3*s.* 9*d.* But R.A.M.C. and other war services are treated better; if there is such income, abatements are taken off in this order: (1) ordinary professional income; (2) unearned; (3) service pay. These abatements are, as far as possible, given effect to in the direct assessment on the practice. But still it is often necessary to send in—

Repayment claims.—They are in time within three years. At present you may go back to April, 1915. Consider whether you have obtained your rights in all the respects above referred to. Do not forget interest paid to any bank. It would be paid without deduction of tax. That means that you are entitled to apply to the Inland Revenue for a refund of an amount equal to the tax on the interest if you did not receive it off in the assessment on your practice. Also, the non-deduction of the interest may upset your whole tax position for the last three years. These things can still be put right for that period.

Rate relief.—The same applies to the tax deducted at the source on dividends, &c., on your own and your wife's investments, including perhaps the house. It is always taken off at the highest rate. During the years in question it has been 3*s.*, 5*s.*, and is now 6*s.* But that is more than people with modest incomes have to bear ultimately. This relief is often given on the Schedule D assessment; but if not, then there must be a repayment claim. Do not be misled by dividends "free of tax." That is only an expression. You pay the tax all the same, and have repayment rights accordingly.

War work.—We have above used this term for brevity, but as this is a matter on which many inquiries might arise it may be better to state that the benefit of the reduced rate of tax, *on the pay only*, is available to all who in the tax year in question have served as (1) a member of any of the naval or military forces of the Crown or of the Air Force, which one is not deemed to have done unless he has served (*a*) on the active list of the Navy, or (*b*) in the Army with the colours, or (*c*) as an airman in the Air Force, or (*d*) as an Army or Air Force officer on full pay or at a rate of pay which appears to the Income-tax Commissioners and the Army or Air Council equivalent to full pay, and that either out of the British Isles or for one month continuously in these isles; or (2) in service of a naval or military character in connexion with the war, for which payment is made out of money provided by Parliament; or (3) in work *abroad* of the British Red Cross, St. John Ambulance, or similar body.

Changes.—We have stated this year's rules. Those for the three previous years have varied a good deal. The rates of tax were lower, so were the children abatements. The wife abatement is new this year. It is only this year that the limit for the family abatements has been raised from £700 to £800.

Partnerships.—The rate of tax is determined by the true tax position of each of the partners. Thus, though 4*s.* 6*d.* is the earned rate on a profit of £2000, if there are two partners equally interested the tax will be charged at 3*s.*, being the £1000 earned rate. But if one takes £1200 and the other £800 tax will be charged on £1200 at 3*s.* 9*d.* and on £800 at 3*s.* That is subject to giving effect to the partners' different abatements; one may have no abatements, and the other's may be important. All which shows that much care is required in seeing that the incidence of the tax is properly regulated in the partnership accounts.

Where one partner is serving in the war the firm's assessment is made up on the footing (1) of charging him on his actual profits of the year; and (2) of charging the other partners on the average, not of the three preceding years, but of the two preceding years and the tax year itself; but this is done only if it benefits them, and in no case can they get off on less than the actual figures of the year.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

A Radio-surgical Aeroplane.

A NEW medical application for the aeroplane has been proposed, no longer to transport the wounded man to hospital, but to carry the surgeon to him. MM. Nemirovsky and Tilmant describe a machine which they call the "aerochir," being a three-seater carrying a pilot, a surgeon, and a radiographer, along with radiological and surgical outfits of small dimensions sufficient to serve for all operations. The dynamo of the aeroplane furnishes the current necessary for radiology and for heating the steriliser. An aluminium folding operation table renders possible the extraction of projectiles by means of the screen. This aerochir is adapted to carry to the front a relieving party equipped with surgical and radiological necessaries in a minimum of time and without risk of being held up on congested roads during an engagement. A dressing station unable to cope with a sudden influx of wounded could thus receive efficacious help within a few minutes.

The Cerebro-spinal Fluid in Typhus.

Dr. Devaux, on his return from Roumania, where he was attached to the French Military Mission, has made an important report on the epidemic of typhus which raged there during the last two winters. He lays great stress upon the neurotropic affinities of the (still unknown) causative agent of the disease, basing his view on the predominance of nervous symptoms at the onset, their persistence throughout the attack, the frequency and gravity of the nervous complications and sequelæ of convalescence, and the wide distribution of lesions in the nerve centres seen at autopsy contrasted with the comparative immunity of the other organs. Cytological examination of the cerebro-spinal fluid is of marked clinical value and has some bearing on prognosis. Leucocytosis occurs early in every case and persists for two to eight months, covering the whole duration of complications. The increase of polynuclear cells is proportional to the gravity of the prognosis. Convalescence is heralded by a rapid diminution in the mononuclear forms, with a predominance of disintegrating cells.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Loss of the "Leinster."

IN the destruction of the R.M.S. *Leinster* last week at least three medical men were on board and have not since been traced, and several nurses have also disappeared. Along with the names of Captain Digby Burns, R.A.M.C., and Dr. R. E. Lee, is that of Sir W. Henry Thompson, D.Sc., whose loss is deeply felt in Belfast. In 1893 when, on the resignation of the late Dr. Peter Redfern, the double chair held by that distinguished teacher of anatomy and physiology in Queen's College, Belfast, was divided into separate departments, Dr. W. H. Thompson was appointed as Dunville professor of physiolcgy, a position he occupied until 1902, when he left Belfast on being selected as King's Professor of Institutes of Medicine in Trinity College, Dublin. He married Miss Isabel Redfern, the eldest daughter of Professor Peter Redfern, and to her and to their son and four daughters the sincerest sympathy of a very large circle of old friends in Belfast and the north of Ireland will be extended in their tragic and terrible loss. Sir W. H. Thompson came to Belfast a complete stranger, with a high record as a Galway College student, and as a demonstrator of anatomy in Trinity College, Dublin. He most worthily maintained and increased his fine early professional promise, and put the new department of physiology in the Belfast School of Medicine in a sound position. A thoroughly hard-working man, of marked independence of character, and determined to succeed, he impressed his colleagues with his great worth, while socially he took his proper position among the people and the affairs of the City of Belfast, following Professor Redfern's admirable example.

Scheme for Medical Attendance on Discharged Disabled Men.

The National Health Insurance Commission (Ireland) have now issued to the members of the medical profession an invitation to join in the scheme for giving medical attendance to discharged disabled sailors, soldiers, marines, and airmen resident in Ireland. The necessity for the scheme arises from the absence of the medical benefit from the National Health Insurance Acts as applied to Ireland. The Government is providing a sum of money equal to a capitation-rate of 12*s.* 6*d.* per head for each discharged disabled man resident in the large towns and 15*s.* for those in the country. The fund for the whole country will go into a common pool, and payment will be made to the practitioners who give treatment in proportion to the work done by each. An elaborate system of token values has been arranged for the several services likely to be rendered.

Royal Academy of Medicine in Ireland.

The annual general meeting of the Royal Academy of Medicine in Ireland was held on Oct. 11th. The number of Fellows increased during the year from 131 to 133, and the number of Members decreased from 17 to 15. The results of elections to the various offices were announced. Sir John Moore, D.Sc., succeeds Dr. R. D. Purefoy as President, and Major F. C. Purser succeeds Sir John Moore as secretary for foreign correspondence.

Oct. 14th.

MEDICINE AND THE LAW.

Pratt and Others v. *The British Medical Association.*

JUDGMENT was delivered by Mr. Justice McCardie on Tuesday last in the case in which several Coventry doctors sued the British Medical Association, and three of its local members, for conspiracy, libel, and slander. The Association had charged the plaintiffs with conduct detrimental to the honour and interests of the profession in carrying on a dispensary at Coventry on principles fundamentally opposed to those approved of by the Coventry division of the Association. His lordship, sitting without a jury, found in favour of the plaintiffs, and awarded damages as follows: For unlawful molestation Dr. Burke £1000, Dr. Holmes £700, and Dr. Pratt £700; for defamation, Dr. Burke £420, Dr. Pratt £630, and Dr. Holmes £360. In delivering judgment Mr. Justice McCardie said that in his view the plaintiffs were boycotted, punished, and pecuniarily damaged without just cause in law, and he felt compelled to come to the reluctant conclusion that the plaintiffs had established actual malice against the defendants. Plaintiffs, he added, must have the costs of the action, save in so far as any costs arose on issues in which they had failed. The terms of injunction remain for consideration.

An Audacious Impostor.

At Liverpool recently a man named Blacklin, 35 years of age, was convicted of giving false information on a registration form, with being an unauthorised person wearing six military decorations, and with wearing uniform so closely resembling that of the Royal Navy that it was calculated to deceive. On the first two charges he received concurrent sentences of six months' imprisonment, and on the third was ordered to pay a fine of £50, with the alternative of imprisonment for three months. He had engaged a room at a hotel in the character of Black, Surgeon, R.N., and had shown a card with the printed inscription, "Surgeon-Major Sir Patrick Black, Bart., M.V.O.," an assumption of titles which would have led to his immediate undoing on the exhibition of such a card to anyone with a glimmer of social knowledge. According to his own tale told to the police, with possible inaccuracies and exaggerations, he had been before the war in turn a messenger boy at the War Office, attached to the R.A.M.C., and a dispenser in New Zealand. He joined the Expeditionary Force and had been wounded twice, and had afterwards selected the name of Patrick Black in the Medical Register because that was a name resembling his own, and he saw opportunities. He had written to the Registrar of the General Medical Council asking him to change the address of that gentleman to his own address. He had no difficulty in obtaining the post of medical officer on board a steamship, and in that capacity had made two voyages. Whatever amount of truth there may be in this story, it points to the necessity for taking every reasonable precaution on the part of those controlling medical appointments. The adoption of the name of a medical practitioner actually on the Register is, however, probably not very often practised, and to obtain the alteration of the address is so obviously likely to lead to speedy detection that the example of Blacklin will hardly be followed by others.

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

SUBSCRIPTIONS TO THE SECOND APPEAL.

THE following subscriptions have been received up to Monday last, Oct. 14th:—

	£	*s.*	*d.*
Miss Agnes M. Cowan, M.O. i/c Q.M.A.A.C.	2	2	0
Dr. W. H. Davies (quarterly)	1	10	0
Mr. E. Spencer Evans (monthly)	0	10	0
Dr. J. W. Papillon (quarterly)	0	10	6
North of England Branch B.M.A.[1]—			
Dr. T. L. Bunting ...	5	5	0
Dr. F. Beaton	1	1	0
Dr. F. Bell	1	0	0
Major L. G. Dillon ...	1	1	0
Dr. J. Chalmers	2	2	0
Dr. O. W. Ogden ...	5	5	0
Dr. A. S. Percival ...	1	1	0
Dr. D. Revie	1	1	0
Dr. G. H. Lowe	1	1	0
Dr. J. Charles	2	2	0
Mr. Morison Johnston	1	1	0
Dr. F. Barker	1	1	0
Dr. H. E. Mortis (second donation this year) ...	3	0	0

[1] Per Dr. J. Don, Hon. Sec.

Subscriptions to the Fund should be sent to the treasurer of the Fund, Dr. H. A. Des Vœux, at 14, Buckingham Gate, London, S.W. 1, and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

SIDMOUTH ISOLATION HOSPITAL.—At the last meeting of the Devon County Council it was reported that the Sidmouth Urban Council had received notice to quit the premises they occupy as a temporary isolation hospital. The Sidmouth council are anxious to provide a permanent isolation hospital for their district, and requested the county council to release them from the scheme for the constitution of a hospital district (including Sidmouth) and provision of an isolation hospital for East Devon. The county council decided to inform the Sidmouth authorities that there was no objection to the provision of a temporary hospital during the war, but that the county scheme would be proceeded with as soon as circumstances permitted.

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue :—

Killed.

Capt. G. A. G. Bonser, R.A.M.C., attached Norfolk Regiment, was educated at Cambridge University and at St. Thomas's Hospital, London, and held appointments at St. Thomas's and also at the Addenbrooke's Hospital, Cambridge. Prior to joining the R.A.M.C. he was in practice at Sutton-in-Ashfield, Notts.
Capt. K. Elmes, R.A.M.C., attached London Regiment, qualified in Ireland in 1916, and joined up forthwith.
Capt. A. Ross, Canadian A.M.C.
Capt. J. A. Stanley, R.A.M.C., attached Royal Warwickshire Regiment, came over with the Canadian Expeditionary Force, and later obtained a commission in the R.A.M.C.
Capt. R. P. Young, Australian A.M.C.
Capt. H. A. Culham, Canadian A.M.C., was educated at the University of Toronto, and qualified in 1910. Prior to joining the Expeditionary Force he was in practice at Viceroy, Moose Jaw.

Died.

Capt. B. H. Leigh, R.A.M.C., qualified at Edinburgh in 1896, and after serving as a surgeon to the Pacific Steam Navigation Company he practised for some years at Southend-on-Sea. Later he retired, and on the outbreak of war resumed his professional work by joining the R.A.M.C. He died at the Epsom War Hospital from illness contracted on foreign service.
Major P. T. Priestley, R.A.M.C., was educated at Birmingham University and qualified in 1912. He held an appointment at the Birmingham General Hospital and later practised at Moseley. He died at Salonika from influenza.

Previously Reported Wounded, now Reported Died of Wounds.

Capt. K. McA. Ross, R.A.M.C., attached Highland Light Infantry, qualified at Glasgow in 1915 and joined up shortly afterwards.

Wounded.

Major T. Ferguson, R.A.M.C.
Capt. G. B. Egerton, R.A.M.C.
Lieut.-Col. H. L. Welch, Australian A.M.C.
Capt. F. G. Banting, Canadian A.M.C.
Capt. A. McA. Blakely, Canadian A.M.C.
Capt. H. S. Berry, R.A.M.C., attd. Royal West Surrey Regt.
Major W. Hunt, M.C., R.A.M.C.
Major T. J. Lindsay, R.A.M.C.
Capt. J. C. Dunn, D.S.O., M.C., D.C.M., R.A.M.C., attached East Yorks Regiment.
Capt. B. M. Tuke, M.C., R.A.M.C., attd. Royal Welsh Fus.
Major J. Vallance, R.A.M.C.
Capt. H. E. B. White, R.A.M.C., attached Yorks Regiment.
Capt. H. G. Young, D.S.O., Canadian A.M.C.
Capt. F. S. Bedale, M.C., R.A.M.C., attached Lancs Fus.
Lieut. A. C. Paterson, R.A.M.C., attd. Royal West Surrey Regiment.
Capt. D. G. K. Turnbull, M.C., Canadian A.M.C.
Capt. H. M. Joseph, R.A.M.C., attached Essex Regt.
Major J. B. Scott, M.C., R.A.M.C.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported :—

Second Lieut. C. J. N. Lambert, M.C., R.F.A., killed in action, elder son of Dr. H. L. Lambert, of Barnes, London, S.W.
Lieut. R. M. Bennett, R.A.F., killed in action, elder son of Dr. J. H. Bennett, of Beckenham.
Second Lieut. J. C. Maurice, Royal Berkshire Regiment, killed in action, youngest son of Brevet Colonel W. J. Maurice, R.A.M.C., T.F., of Reading.
Lieut. E. T. Halford, R.E., died at Aldershot, son of the late Dr. E. Halford, of Hammersmith, London, S.W.
Second Lieut. H. F. Weiss, London Regiment, killed in action, only son of the late Mr. H. F. Weiss, F.R.C.S., of Hanover-square, London, S.W.
Second Lieut. Rev. R. H. A. Cotton, A.S.C., youngest son of Dr. C. Cotton, of Canterbury.
Second Lieut. J. S. Ricketts, R.F.A., eldest son of the late Dr. T. F. Ricketts, of the Joyce Green Hospital, Dartford.

OBITUARY OF THE WAR.

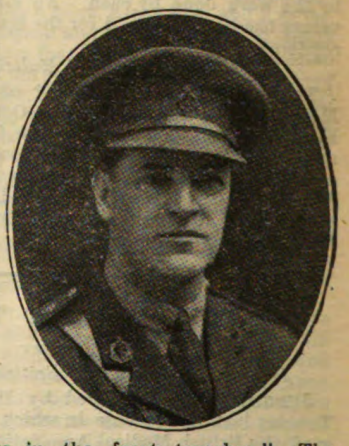
ALEXANDER JOHNSTON, M.D. GLASG., D.P.H. CAMB.,
MAJOR, ROYAL ARMY MEDICAL CORPS.

Major A. Johnston, who died at a nursing home in Glasgow on Sept. 22nd, was son of the late Robert Johnston, of Dumbarton. He was educated at Glasgow Academy and at the University where he graduated M.B., C.M. in 1883, subsequently holding resident posts at Manchester Royal Infirmary and Monsall Hospital. He then travelled widely in Europe and America before settling down to his life-work as physician-superintendent of the Glasgow City Hospitals, a position which he held for 22 years. He was also deputy medical officer of health and lecturer on infectious diseases in the University, being responsible for a number of important papers and reports on epidemiology. In April, 1915, he was appointed officer in command of the Thornhill Military Hospital, continuing until July last, when he underwent an operation which unexpectedly had a fatal termination.

Major Johnston was a man of many interests. He was deeply read in Scottish history. He was an active chairman of the Glasgow Eastern Medical Society. Of a kindly disposition, he had the reputation of being fearless in the discharge of his duty and careful for the well-being of those under him. His widow, the eldest daughter of Mr. Richard Allan, medical officer of health for Dumbarton, survives him.

BERNARD CHARLES TENNENT, M.D., CH.B. EDIN.,
MILITARY CROSS WITH BAR,
MAJOR, ROYAL ARMY MEDICAL CORPS.

Major B. C. Tennent, who was killed in action on August 22nd, was son of the late Rev. E. C. Tennent, of Martinborough, N.Z. After graduating in medicine at Edinburgh University and holding resident appointments in London at the Great Northern and Ormond-street Hospitals, he went out to New Zealand and settled in Wellington. Returning to this country on the outbreak of war, he received a commission in the R.A.M.C. in January, 1915, serving for three and a half years on various fronts. The Military Cross was awarded to him "for conspicuous gallantry and devotion to duty in constantly exposing himself with the utmost fearlessness under heavy shell fire in order to visit his posts in the front trenches." The addition of the bar was further proof of his courage and presence of mind. A friend who knew Major Tennent well writes of his combination of manly and athletic qualities with gentleness and grace of spirit. Major Tennent married in June, 1917, Daisy, youngest daughter of the late C. C. Skarratt.



"OUR DAY," 1918.—The King and Queen have each subscribed £1000 to the funds of the Red Cross for "Our Day," Oct. 24th. The Lord Mayor has asked the City of London to subscribe £1,000,000 for "Our Day."

THE HONOURS LIST.

The *Distinguished Service Cross*, for services in the destroyer action in the Adriatic on the night of April 22nd–23rd, 1918, has been conferred upon—

Surg. Prob. Charles C. Elliott, R.N.V.R.

He carried out his duties in attending wounded under heavy fire and difficult conditions. Although he was suffering from a painful sprained wrist, his skilful work undoubtedly saved several lives. His conduct was an example and encouragement to all on board.

And for services in the Battle of Jutland on May 31st, 1916, upon—

Surg. Prob. Alexander Joe, R.N.V.R.

Medical Officer of H.M.S. *Nestor*. He behaved with the greatest coolness under fire, tending the wounded single-handed both in *Nestor* and later on board a German destroyer. His conduct was highly praiseworthy throughout.

The following appointments to the *Order of the British Empire* are announced :—

Officers.—Dr. Mary Booth (organised Friendly Union of Soldiers' Wives and Soldiers' Club, Sydney); Lt.-Col. A. S. Herbert, New Zealand M.C. (for special services in connexion with military hospitals at Rotorua); Lt.-Col. H. H. Y. Hearsey, Principal Medical Officer to the Civil Government and Assistant Director of Military Medical Services, Nyasaland Protectorate.

Members.—Dr. C. Akerman (Natal); Dr. P. P. J. Ganteaume, Mayor of East London, S.A.; Dr. R. Strachan, Mayor of Germiston, S.A.; Dr. J. B. Addison, Chief Medical Officer, Colony of Seychelles (for services in connexion with war charities); Dr. R. Howard, of the Universities Mission to Central Africa (for voluntary service in attending sick and wounded native soldiers and carriers, Zanzibar); Surgeon-Major John Hutson, Public Health Inspector, Barbados, and Principal Medical Officer to the Barbados Defence Force; and Dr. J. Lochhead, Surgeon, Colonial Hospital, Gibraltar (for services to merchant seamen).

MENTIONED IN DESPATCHES.

The names of the following medical officers are added to recent despatches :—

Maj.-Gen. W. G. A. Bedford, C.B., C.M.G., A.M.S.; Temp. Capt. M. B. Arnold, R.A.M.C.; Capt. B. A. Odlum, R.A.M.C.; Lt. (temp. Capt.) W. H. Ferguson, R.A.M.C.; Temp. Capt. A. C. Mann, M.C., R.A.M.C.; Col. R. M. Simpson, Canadian A.M.C.; Temp. Maj. J. J. Abraham, R.A.M.C.; Lt.-Col. (temp. Col.) G. A. T. Bray, R.A.M.C.; Maj. (temp. Lt.-Col.) M. Dunning, R.A.M.C.; Col. E. G. R. Evatt, R.A.M.C.; Capt. (acting Lt.-Col.) E. C. Lambkin, R.A.M.C.; Temp. Lt.-Col. H. Wade, R.A.M.C.; Lt.-Col. R. T. Brown, D.S.O., R.A.M.C.; Maj. (temp. Lt.-Col.) P. S. Clarke, South African M.C.; Capt. T. S. Dunn, East African Med. Service; Temp. Maj. W. J. Gow, R.A.M.C.; Maj. R. S. Kennedy, M.C., I.M.S.; Capt. (acting Lt.-Col.) J. A. Manifold, R.A.M.C.; Lt.-Col. P. W. O'Gorman, I.M.S.; Surg.-Prob J. E. Deane, R.N.V.R.

BROUGHT TO NOTICE.

The names of Major W. McConaghy, R.A.M.C., and of Temp. Capt. W. N. Montgomery, R.A.M.C., have been brought to the notice of the Secretary of State for War for valuable services rendered in connexion with military operations in Hedjaz.

FOREIGN DECORATIONS.

French.

Croix de Guerre.—Temp. Capt. J. B. McFarland, M.C., R.A.M.C.; Capt. (acting Maj.) R. R. Lovell, R.A.M.C.; Capt. M. J. Holmes, Australian A.M.C.; Maj. (acting Lt.-Col.) H. H. A. Emerson, D.S.O., R.A.M.C.; Capt. S. R. Foster, M.C., R.A.M.C.; Maj. (temp. Lt.-Col.) W. J. S. Harvey, D.S.O., R.A.M.C.; Maj. (temp. Lt.-Col.) F. D. G. Howell, D.S.O., M.C., R.A.M.C.; Capt. P. McEwan, R.A.M.C.; Maj. (acting Lt.-Col.) P. J. Marett, R.A.M.C.; Capt. (acting Maj.) J. J. McI. Shaw, M.C., R.A.M.C.; Capt. (acting Maj.) W. L. Webster, R.A.M.C.; Temp Capt. A. B. Cluckie, R.A.M.C.

Légion d'Honneur: Croix de Chevalier.—Col. H. R. Casgrain, Canadian A.M.C.; Hon. Maj. C. F. Skipper, Canadian A.M.C.

Portuguese.

Military Order of Avis, 2nd Class.—Major W. H. G. H. Best, R.A.M.C.

Hellenic.

Order of the Redeemer.—2nd Class, Grand Commander: Surg.-Gen. Sir H. R. Whitehead, K.C.B. *3rd Class, Commander:* Lieut.-Col. A. R. Aldridge, C.B., C.S.I., C.M.G., R.A.M.C. *5th Class, Cavalier:* Capt. J. P. Litt, R.A.M.C.

Japanese.

Order of the Sacred Treasure, 3rd Class.—Col. T. J. R. Lucas, C.B. (retired pay).

INFLUENZA ON AMERICAN TRANSPORTS.

Alarming accounts have been current regarding the prevalence and fatality of influenza among the U.S.A. troops on their way across the Atlantic, especially on the ill-fated s.s. *Otranto*. There has evidently been some confusion between the number of cases and the number of deaths. Regarding the *Otranto*, we are in a position to state that up to the time of arrival in English waters there had been about 50 cases of influenza and pneumonia. Four of these cases of pneumonia proved fatal. Among the survivors, a considerable number of whom were injured in the accident, deaths have occurred from pneumonia due to exposure during rescue. But this mortality should, of course, not be credited to the prevailing epidemic.

MAJOR-GENERAL M. W. IRELAND, THE NEW SURGEON-GENERAL, U.S.A.

As we announced last week, Major-General Merritte W. Ireland has been appointed Surgeon-General to the United States Forces. General Ireland entered the Medical Corps of the American Army in 1891 as a first lieutenant. He was promoted to the grade of captain in 1896. During the Spanish-American War he was with the Fifth Army Corps expedition, which fought the battle of Santiago and received the surrender of the city. Shortly after the conclusion of the Cuban campaign General Ireland was sent to the Philippine Islands as major and surgeon of the 35th Infantry, U.S. Volunteers. Soon after arrival there he was detached from regimental service and placed in charge of the Medical Supply Depôt in the city of Manila, which he administered with great success. Returning to the United States at the end of two years, he was called to the Surgeon-General's office in Washington, D.C., in 1902, under Surgeon-General O'Reilly, and placed in charge of the personnel division of that office, which he administered most successfully until 1912, when he was again sent to the Philippines and put in charge of a large hospital in the vicinity of the city of Manila, located at Fort William McKinley.

General Ireland returned to the United States in 1915, and at the time that America entered the present war was the commanding officer of the large base hospital at Fort Sam Houston, Texas. Detached from this duty, he accompanied General Pershing to Europe as a member of his staff and filled the position of assistant to the chief surgeon of the American Expeditionary Forces from July, 1917, until March, 1918, when he was promoted to chief surgeon of the command while yet a colonel. His promotion to the grade of brigadier-general followed in May of the present year, and he attained the grade of major-general in the Medical Corps last August. General Ireland returns to the United States very shortly to take up the duties of his new position at U.S. Army Headquarters at Washington. He has always been a man of untiring energy and acute judgment in the conduct of affairs, and the Medical Corps under his strong guidance will acquit itself well in the great endeavour which it has now before it.

THE INCOME-TAX OF MEDICAL WOMEN ATTACHED TO THE R.A.M.C.

Dr. Louisa Garrett Anderson has written calling attention to the fact that medical women attached to the R.A.M.C. do the work of commissioned officers when enforcing discipline in such a hospital as the General Military Hospital, Endell-street, perform the surgical duties of officers in the R.A.M.C., and receive the same rate of pay, but because they do this without having commissions or honorary commissions they are not entitled to the Service rate of income-tax. Where abatement is made in the case of men on the ground that they are doing work of a military character, it is not easy to see why work of the same kind performed by women should not entitle them to the same privilege.

URBAN VITAL STATISTICS.

VITAL STATISTICS OF LONDON DURING SEPTEMBER, 1918.

In the accompanying table will be found summarised complete statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious disease it appears that the number of persons reported to be suffering from one or other of the ten diseases specified in the table was equal to an annual rate of 4·7 per 1000 of the population, estimated at 4,026,901 persons; in the three preceding months the rates had been 4·5, 3·5, and 3·2 per 1000. No case of any of these diseases was notified during the month of September in the City of London. Among the metropolitan boroughs the lowest rates were recorded in Chelsea, the City of Westminster, St. Marylebone, Hampstead, and Holborn; and the highest rates in Finsbury, Bethnal Green, Stepney, Southwark, Bermondsey, and Greenwich. The prevalence of scarlet fever was 60 per cent. higher than in the preceding month; this disease was proportionally most prevalent in Finsbury, Bethnal Green, Stepney, Southwark, Bermondsey, and Lambeth. The Metropolitan Asylums Hospitals contained 931 scarlet fever patients at the end of the month, against 846, 753, and 690 at the end of the three preceding months; the weekly admissions averaged 164, against 127, 105, and 101 in the three preceding months. The prevalence of diphtheria was about 50 per cent. higher than in August; the greatest proportional prevalence of this disease was recorded in St. Pancras, Hackney, Bethnal Green, Stepney, Southwark, Bermondsey,

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING SEPTEMBER, 1918.

(Specially compiled for THE LANCET.)

CITIES AND BOROUGHS.	Estimated civil population, 1917.	Notified Cases of Infectious Disease.											Deaths from Principal Infectious Diseases.

* Including membranous croup.

and Greenwich. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1179, 918, and 886 at the end of the three preceding months, numbered 1051 at the end of September; the weekly admissions averaged 166, against 165, 122, and 107 in the three preceding months. The prevalence of enteric fever was about equal to that in the two preceding months; of the 28 cases notified in September, 5 belonged to Islington, 5 to Wandsworth, and 2 each to Paddington, Fulham, Hackney, Greenwich, Lewisham, and Woolwich. There were 43 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 40, 23, and 32 at the end of the three preceding months; the weekly admissions averaged 6, against 6, 4, and 6 in the three preceding months. Erysipelas was proportionally most prevalent in St. Pancras, Islington, Finsbury, Bethnal Green, and Southwark. The 10 cases of puerperal fever notified during the month included 3 in Hackney and 2 in Woolwich. Of the 8 cases of cerebro-spinal meningitis 2 belonged to Wandsworth.

The mortality statistics in the table relate to the deaths of persons actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the four weeks ended Sept. 28th the deaths of 3537 London residents were registered, equal to an annual rate of 11·4 per 1000; in the three preceding months the rates had been 11·8, 14·8, and 10·1 per 1000. The death-rates ranged in September from 6·5 in the City of London, 8·8 in Hampstead, 9·2 in the City of Westminster, 9·3 in Woolwich, and 9·9 in Stoke Newington, to 12·7 in St. Pancras, 12·8 in St. Marylebone, 13·7 in Bermondsey, 13·8 in Bethnal Green, 14·2 in Poplar, and 16·2 in Holborn. The 3537 deaths from all causes included 394 which were referred to the principal infectious diseases; of these, 18 resulted from measles, 9 from scarlet fever, 29 from diphtheria, 28 from whooping-cough, 7 from enteric fever, and 303 from diarrhœa and enteritis among children under 2 years of age. Among the metropolitan boroughs the lowest death-rates from these diseases were recorded in Paddington, Chelsea, the City of Westminster, St. Marylebone, Hampstead, and Stoke Newington; and the highest in Shoreditch, Bethnal Green, Stepney, Poplar, Bermondsey, and Woolwich. The 18 deaths from measles were 19 below the average number in the corresponding period of the five preceding years, and included 6 in St. Pancras and 3 in Bermondsey. The 9 fatal cases of scarlet fever showed a decline of 2 from the average; of these, 3 deaths belonged to Lambeth. The 29 deaths from diphtheria were 10 less than the average, and included 4 in Stepney, 4 in Woolwich, 3 in Islington, and 3 in Poplar. The deaths from whooping-cough numbered 28, and showed a decline of 13 from the average; of these, 4 belonged to Islington, 3 to Bermondsey, and 3 to Battersea. The 7 fatal cases of enteric fever were one less than the average number; 2 deaths belonged to St. Pancras. The 303 deaths from diarrhœa and enteritis among children under 2 years of age were less than a half of the average; this disease was proportionally most fatal in Fulham, Hackney, Shoreditch, Bethnal Green, Stepney, and Poplar. In conclusion, it may be stated that the aggregate mortality in London in September from these principal infectious diseases was 51 per cent. below the average.

(Week ended Oct. 12th, 1918.)

English and Welsh Towns.—In the 98 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality was 15·1, against 11·4 and 12·6 per 1000 in the two preceding weeks. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 14·0, or 1·3 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 4·7 in Gillingham, 5·4 in Barnsley and in Rhondda, and 6·2 in Ilford, to 33·5 in Birkenhead, 41·6 in Southampton, 43·4 in Exeter, and 44·1 in Portsmouth. The principal epidemic diseases caused 207 deaths, which corresponded to an annual rate of 0·7 per 1000, and included 96 from infantile diarrhœa, 49 from diphtheria, 22 from whooping-cough, 21 from measles, 15 from scarlet fever, and 4 from enteric fever. The deaths from diarrhœa, which had declined from 435 to 186 in the six preceding weeks, further fell to 96, and were 147 below the number registered in the corresponding week of last year; 30 deaths belonged to London, 7 to Liverpool, and 6 each to Birmingham and Sheffield. The 1148 cases of scarlet fever and 1182 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 129 and 57 above the respective numbers remaining at the end of the previous week. The deaths from influenza in London numbered 89, against 17 in each of the two preceding weeks. The causes of 47 deaths in the 96 towns were uncertified, of which 12 were registered in Birmingham, 10 in Liverpool, 5 in Walthamstow, and 3 in Leicester.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,000,000 persons, the annual rate of mortality, which had increased from 10·6 to 19·0 in the four preceding weeks, further rose to 21·7 per 1000. Of the 1141 deaths from all causes, 45 were classified to influenza, which was also stated as a contributory cause in 339 deaths classified to other diseases; in the previous week these numbers were 35 and 159 respectively. The 767 deaths in Glasgow corresponded to an annual rate of 35·9 per 1000, and included 11 from whooping-cough, 5 from infantile diarrhœa, 4 from diphtheria, and 1 from measles. The 74 deaths in Edinburgh were equal to a rate of 11·6 per 1000, and included 3 each from scarlet fever and diphtheria, 2 from infantile diarrhœa, and 1 from measles.

Irish Towns.—The 188 deaths in Dublin corresponded to an annual rate of 24·6, or 3·3 per 1000 above that recorded in the previous week, and included 7 from infantile diarrhœa, and 1 each from enteric fever, scarlet fever, and diphtheria. The 106 deaths in Belfast were equal to a rate of 14·1 per 1000, and included 4 from infantile diarrhœa and 1 each from enteric fever and measles.

BRITISH HOSPITALS ASSOCIATION.—A conference will be held at St. Thomas's Hospital, London, to-day (Friday, Oct. 18th) at 3 P.M. to consider the proposal to create a Ministry of Health, in its relation to the voluntary hospitals. Lord Sandhurst will preside.

Obituary.

ALFRED HUME GRIFFITH, M.D. EDIN., D.P.H. CAMB.,

SUPERINTENDENT OF THE LINGFIELD COLONY FOR EPILEPTICS.

Dr. Alfred Hume Griffith, whose death occurred at the early age of 43 years, was second son of the late Rev. Edward Moule Griffith, and received his preliminary education at Persse School, Cambridge, and at Totnes and Bedford Grammar Schools. The missionary spirit took hold of him in the earlier years of his manhood; and it was in order to fit himself to be of service to others that he decided to enter the medical profession. With this intent he matriculated at Edinburgh in 1893, graduating M.B., Ch.B. six years later. In 1900 he married Mary, daughter of George Welchman, of Cullompton, and went out to take temporary charge of the Persian medical mission work at Ispahan. His pioneer work in Kerman, relinquished with reluctance on account of his wife's ill-health, was successful in breaking down hostile fanaticism of a kind which has often cost the lives of those who faced it. After a year in charge of the Medical Mission at Yezd Dr. Griffith finally left Persia in 1903, and after a short furlough, largely spent in study at Edinburgh (during which he took his M.D. degree), he offered himself for work in Palestine, and was appointed to the C.M.S. Hospital at Nablus, obtaining, while passing through Constantinople, the Turkish certificate enabling him to practise medicine throughout the Turkish Empire. In 1904 he moved on to Mosul in Mesopotamia and founded a hospital, where, assisted only by native men whom he himself had trained, he performed a large amount of surgical work. A collection of urinary calculi was presented by him to the Museum at Cambridge. But his strength proving unequal to the great strain thus made upon it, he was invalided home in 1908.

After a period of further study, during which he obtained the Cambridge D.P.H., Dr. Griffith was appointed, in October, 1910, superintendent and medical officer of Lingfield Colony for Epileptics, one of the several homes established by the National Union for Christian Social Service. Although impaired health necessarily restricted his energies, he brought to this task a union of qualities exactly suited for the successful handling and treatment in colony life of a malady and temperament admittedly presenting peculiar difficulties. Himself of athletic instincts—he was an Edinburgh "blue" in football, and when abroad never so happy as in the saddle—he saw to it that his patients as far as possible lived an open-air life, abundantly supplied with occupation, recreation, and hobbies.

He was an omnivorous reader and kept himself abreast of medical research, his own powers of observation being displayed in the contributions he made to medical literature, including articles on Hereditary Factors in Epilepsy (1911), Mental Tests in Defective Children (1916), and a chapter on the Epileptic in Kelynack's "Human Derelicts." He also wrote the chapters on Medical Missions in his wife's book, "Behind the Veil in Persia and Turkish Arabia." Recently Dr. Griffith had been much occupied with the institutional treatment and training of discharged sailors and soldiers suffering from epilepsy by arrangement with the Ministry of Pensions. Experience has shown that this is a specially difficult problem, many of the men failing to realise their disability, and being, not unnaturally, impatient of prolonged treatment. But Dr. Griffith knew his men; he possessed the technical skill requisite to obtain insight into their individual peculiarities, and often into the origin of the latter; and his sympathy with them and determination to restore them to a normal civilian life engendered, besides affection, a loyalty to régime that explains much of his success. Apart from his special work, Dr. Griffith had many projects in view for the development of the Lingfield Colony's sphere of usefulness, and the carrying of these into effect will be the best tribute to his memory. He leaves a widow and a young daughter.

AT their meeting on Oct. 8th the Portsmouth town council resolved unanimously to raise the salary of their medical officer of health, Dr. A. Mearns Fraser, from £800 to £1000 per annum "in view of the satisfactory manner in which he has performed his duties during a period of 23 years."

Correspondence.

"Audi alteram partem."

WAR EMERGENCY FUND OF THE R.M.B.F.

To the Editor of THE LANCET.

SIR,—I am very glad that Sir W. Watson Cheyne has drawn attention (THE LANCET, Oct. 12th) to the urgent need of providing without delay help for the members of our profession who, on returning from the war, will have to start in practice anew. Some provision for the financial need has already been made. Two years ago the War Emergency Fund of the Royal Medical Benevolent Fund was started, and about £20,000 have already been collected and temporarily invested. This Fund has been raised to help those who are in financial difficulties as the result of their war service, and to assist them in re-starting in practice. It is obviously most desirable not to duplicate funds of this kind, and I venture to urge all those who are moved by Sir W. Watson Cheyne's appeal to rally to the support of the War Emergency Fund and send subscriptions to the treasurer, addressed to 11, Chandos-street, Cavendish-square, W. 1.

It is impossible to tell what amount of money will be needed; it is certain that we shall want much more than we have at present, and we are appealing now for a further £10,000. When our colleagues returning from the front need help to resume their civil work they will want it promptly and it must be ample in amount. We must be prepared with large funds, and there is no time to lose if we are to be ready for the emergency.—I am, Sir, yours faithfully,

ALFRED PEARCE GOULD,
Chairman of the War Emergency Fund Committee.

Queen Anne-street, W., Oct. 13th, 1918.

THE CAMPAIGN FOR THE PREVENTION OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—The American Commission for the Prevention of Tuberculosis in France (the Rockefeller Foundation) has organised a very successful campaign against tuberculosis among the civil population in France by means of dispensaries, caravans, lectures, cartoons, and similar propaganda. Professor Selskar M. Gunn, one of the Associate Directors of the above Commission, will give a lecture, illustrated by lantern slides, at the annual meeting of the National Association for the Prevention of Consumption and Other Forms of Tuberculosis, on Tuesday, Oct. 29th, at 4 P.M., in the Large Hall, 20, Hanover-square, W. He will show the methods the Commission is using in France, which should be very interesting to us in this country.

Anyone wishing to attend the meeting should apply to the secretary of the National Association for the Prevention of Consumption and Other Forms of Tuberculosis, 20, Hanover-square, W. 1, for a ticket.—I am, Sir, yours faithfully,

J. J. PERKINS,
Hon. Secretary.

Oct. 15th, 1918.

MEDICAL MEN IN PARLIAMENT: SIR WILMOT HERRINGHAM'S CANDIDATURE.

To the Editor of THE LANCET.

SIR,—I see that a meeting has been held, under the chairmanship of Sir Henry Morris, to promote the candidature of medical men in the coming General Election. It will be important to have doctors in Parliament in view of the many questions which will press for attention concerning the prevention of disease and of infant mortality, sanitary housing, the treatment of the sick, and the establishment of disabled soldiers in suitable positions. The creation of a Ministry of Health and the proper position of medical advisers in local administration are equally important topics. It has been pointed out that the Universities are specially suitable for our candidates, since they are, or should be, more free than other constituencies from a narrow party spirit.

On these grounds I have accepted an invitation to stand for the University of London at the coming election.

I am, Sir, yours faithfully,

W. P. HERRINGHAM,
Major-General (Temp.); Consulting Physician to the Forces in France.

G.H.Q., France, Oct. 11th, 1918.

MEDICAL MEN IN PARLIAMENT.

To the Editor of THE LANCET.

SIR,—Will you allow me to say that I am in entire agreement with Lieutenant-Colonel M. A. Collins's suggestion (THE LANCET, Oct. 12th) that the Medico-Psychological Association should be represented on the Executive Committee formed on Oct. 1st "to further the election of medical men to the House of Commons." I know well the importance of that branch of medicine in its relation to State legislation, and I will take the first available opportunity to endeavour to attain his object. When Colonel Collins raised the question it was getting very late, the meeting had lasted considerably over two hours and was beginning to disperse, and I wished to avoid the risk of prolonged delay and discussion which similar suggestions made by members specially interested in other branches of medicine and surgery would certainly have caused.

I am, Sir, yours faithfully,

HENRY MORRIS.

Cavendish-square, London, W., Oct. 14th, 1918.

To the Editor of THE LANCET.

SIR,—Can anyone inform me why in the recently formed committee for "taking such steps as may be possible to further the election of medical men to the House of Commons," there is no representative of the Society of Apothecaries?—I am, Sir, yours faithfully,

WILLIAM H. KESTEVEN, L.S.A.

Kingston Hill, Surrey, Oct. 12th, 1918.

NOTIFICATION OF INDIGENOUS MALARIA.

To the Editor of THE LANCET.

SIR,—I should like to add a word to Professor Arthur Hall's letter of warning in your issue of Oct. 12th concerning the introduction of malaria into this country. Hitherto cases of malaria have been comparatively few, and the chance, therefore, of any given anopheline mosquito coming into contact with any given case has been somewhat remote. The conditions are now, or will shortly be, greatly changed; and I am under the impression that people generally are not fully alive to the very wide distribution of the anopheline group of mosquitoes in these islands.

During the past two years I have paid considerable attention to this subject in my own district, and have discovered that in the woods and river valleys in the eastern portion of this county anophelines are readily to be found, most commonly *A. maculipennis;* but this summer I have also found colonies of *A. plumbeus*, and it is quite certain that the south-eastern portion of England is the normal habitat of a large number of anopheline mosquitoes, as is shown in the British Museum map, which probably understates the case owing to paucity of observers. I regret that the limitation of petrol has this year circumscribed my own observation to a much narrower field.

I am, Sir, yours faithfully,

JAMES R. WHITWELL.

St. Audry's Hospital, Melton, Suffolk, Oct. 14th, 1918.

CHRONIC INTESTINAL STASIS.

To the Editor of THE LANCET.

SIR,—I can lay very little claim to the title of anatomist, and none at all to that of anthropologist. I am, therefore, clearly not in a position to discuss with Captain F. Wood-Jones the interesting question as to whether or not the Hominidæ ever passed through a quadrupedal stage. I was taught that they did, but that proves nothing.

In the matter of "the damnable heritage of the colon," however, I crave a further word. If I have correctly understood your correspondent, he maintains that the short colon of the carnivora is adapted to the discipline of fasting, and the long colon of the herbivora to the otiose absorption of raw vegetables. I am quite content to take it at that. Now, man is furnished with a very long colon; but, in flagrant contravention of the formula, he eats flesh foods. Moreover, he cooks these flesh foods. He also cooks his vegetables, and mainly in such a manner as completely to destroy their vitamines. Such a degree of civilisation in matters dietetic may be very æsthetic, but it is obviously unsuited to the colon with which Providence has provided him. His colon, therefore, gives him very serious trouble. If he would avoid this trouble he must select one of two alternatives. He must either adapt his diet to his colon, or he must adapt his colon to his diet. The first he can do by confining himself to raw vegetables; the second he can accomplish either by fasting or by having his colon shortened. He declines to live entirely on raw vegetables; and, having tried it, I cannot find it in me to blame him. The decision between fasting and colon removing is a mere matter of taste. Personally, I prefer the former.

I am, Sir, yours faithfully,

Harley-street, W., Oct. 12th, 1918. LEONARD WILLIAMS.

SENSORY CHANGES IN THE DIAGNOSIS OF TRENCH FEVER.

To the Editor of THE LANCET.

SIR,—The paper by Major Carmalt Jones in your issue of Oct. 5th is of very great interest. He has placed in our hands a helpful method of retrospective diagnosis of the original cause of much "debility." It would be interesting to know whether the absence of areas of increased sensitiveness in 20 per cent. of his series of 500 cases was ever associated with the presence of analgesic patches. Since my attention was called to such cases by Captain J. A. Hartley, R.A.M.C.(T.), I have investigated a large number and have found that it is quite common for men in the middle and later stages of the disease to have areas of analgesia to pin-prick. This loss of sensibility varies in degree from a mere blunting of sensation to complete analgesia. The most common situations for this phenomenon are the outer surface of the calf, the infrapatellar, scapular, and deltoid regions; it has not been found in the skin of the face, neck, or trunk. Circumstances have prevented investigation of the total duration of this sensory loss, but it has sometimes been found five weeks after the onset of the disease, and may still be present in a proportion of chronic cases readmitted to hospital from convalescent camps.

I am, Sir, yours faithfully,

C. E SUNDELL,

France, Oct. 9th, 1918. Captain, R.A.M.C.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations recently held the following candidates were successful in the subjects indicated:—

PRIMARY EXAMINATION, PART II.

Anatomy.—J. W. Alden, Oxford; A. B. Aldred, Guy's Hosp.; M. Bulrski, London Hosp.; F. J. Darbyshire, King's Coll. Hosp.; G. Fraser-Smith, Middlesex Hosp.; E. W. Hicks, St. Thomas's Hosp.; R. J. Hooker, Guy's Hosp.; C. F. Long, Bristol; and A. Senn, London Hosp.

Physiology.—A. B. Aldred, Guy's Hosp.; M. Bulrski, London Hosp.; H. V. Croucher, Guy's Hosp.; F. J. Darbyshire, King's Coll. Hosp.; R. Erskine Gray and E. W. Hicks, St. Thomas's Hosp.; R. J. Hooker, Guy's Hosp.; C. F. Long, Bristol; and A. Senn, London Hosp.

CENTRAL MIDWIVES BOARD.—A meeting of the Central Midwives Board was held at Queen Anne's Gate Buildings, Westminster, on Oct. 10th, with Sir Francis H. Champneys in the chair.—A letter was considered from the Local Government Board asking the Central Midwives Board to consider the advisability of framing a new Rule E. 22 (1) (*f*) in terms similar to the corresponding rule of the Central Midwives Board for Scotland, which requires a midwife to notify the local supervising authority in the following case—* (*f*) "Artificial feeding"—whenever under Rule 19 (*b*) she has advised the substitution of artificial feeding for breast feeding. The Board decided that the question be adjourned to the next meeting of the Board.—A letter was considered from the medical officer of health for the county of Durham asking whether the Board would object to the County Council supplying midwives within their jurisdiction with collosum argentum for the treatment of the eyes of newly born infants. The Board decided that the medical officer of health for the county of Durham be informed that the Board has designedly refrained from recommending in the rules the use of any specific drug for the treatment of the eyes of newly born infants. It sees no objection to the course proposed by the medical officer of health for the county of Durham.—A letter was considered from the acting county medical officer of health for the West Riding of Yorkshire bringing to the notice of the Board a scheme of maternity

and child welfare now in course of organisation by the county council of the West Riding, and asking the Board to approve S. Faith's Rescue and Maternity Home, Leeds, as a branch of the West Riding Nurses' Home with a view to enabling the latter institution to utilise for the training of its pupils the midwifery cases undertaken by the midwives at S. Faith's. The Board decided, in view of the altered condition of the circumstances set forth in the letter of the acting county medical officer, to consider an application for approval to train pupil midwives from the lady superintendent or matron (being certified midwives) of S. Faith's Rescue and Maternity Home, Leeds, provided that the whole of the attendance on labours of such pupils is not carried out at the home.

LONDON HOSPITAL MEDICAL COLLEGE.—The "Price" and Entrance Scholarships in Science (value £100 and £50 respectively) have been divided between G. N. Golden, J. H. Andre, and K. W. Todd.

A COURSE of three public lectures on "France's Share in the Progress of Science" will be delivered at University College on Tuesdays, Oct. 22nd and 29th and Nov. 5th, at 5 P.M., by M. Henri L. Joly, Professeur de Sciences Physiques et Naturelles au Lycée Français (Institut Français du Royaume Uni). The chair will be taken at the first lecture by Professor J. Norman Collie, D.Sc., F.R.S. A leaflet containing full particulars of the lectures may be obtained by sending a stamped addressed envelope to the Publications Secretary, University College, London (Gower-street, W.C. 1).

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee, held on Oct. 8th, 21 cases were considered and £206 1s. voted to 16 of the applicants. The following is a summary of some of the cases relieved:—

L.R.C.S. Irel., aged 72, married, who practised at Redland, Bristol. Owing to ill-health quite unable to practise, and has no savings. Only income interest on £200 on deposit at the bank. This was received from insurance on the death of his son. Voted £26 in 12 instalments.—Widow, aged 57, of M.B. Glasg. who practised in South Wales and died in August, 1918. Applicant was left unprovided for at her husband's death. Has three children, son 24, and twin daughters aged 22. Rent £30. Voted £5.—Widow, aged 70, of L.R.C.P. Edin. who practised at Bervie and died in June, 1918. Applicant's husband had been helped by the Fund for the last two years. She is now a confirmed invalid, and her only income is occasional gifts from her two children. Rent £14. Voted £12 in 12 instalments.—Daughter, aged 61, of M.R.C.S. Eng. who practised at Wymondham and died in 1870. Applicant lost all her income through a defaulting trustee, and a lady who helped her has recently died. Lives with a family who provide board, but no pay. Relieved ten times. £64. Voted £12 in 12 instalments.—Wife, aged 39, of M.R.C.S. Eng. who practised at Bournemouth and is now in an asylum. Applicant is suffering from tuberculosis. Has two children, now aged 17 and 12, living with relations, who also provide for her husband's maintenance. Relieved five times. £67 10s. Voted £12 in six instalments.—Daughter, aged 50, of M.D. Edin. who practised at Southampton and died in 1888. Applicant is a trained midwife, but owing to ill health is unable to follow her occupation. Friends provide 12s. 6d. per week, but this is insufficient to pay for board and lodging. Relieved five times, £36. Voted £12 in 12 instalments.—Daughter, aged 52, of M.D. Glasg. who practised at Glasgow and died in 1897. Applicant used to earn a little as housekeeper, but owing to the severe illness of her invalid mother, aged 78, has had to give up work to attend to her. Relieved four times, £40. Voted £10.—Widow, aged 73, of L.R.C.S. Irel. who practised at Walworth and died in 1915. Was left entirely without means. Receives Old Age Pension, £7 16s. Eldest daughter allows 2s. 6d. per week, and youngest daughter, who earns 35s., lives with mother. Relieved four times, £38. Voted £12 in 12 instalments.—Widow, aged 82, of M.R.C.S. Eng. who practised at Woodford, Essex, and died in 1913. Applicant was left without means, and friends subscribed to a fund, but this is now almost exhausted. Has four children, son, aged 47, and daughter, married, unable to help. Daughter, aged 45, is at home looking after mother, and daughter, aged 48, a munition worker, earns 35s. and pays 15s. per week towards household expenses. Relieved once, £18, in September, 1913. Voted £18 in 12 instalments.

Subscriptions may be sent to the acting Honorary Treasurer, Dr. Samuel West, at 11, Chandos-street, Cavendish-square, London, W. 1.

CAMBRIDGESHIRE TUBERCULOSIS COLONY.—On Oct. 9th the Queen, accompanied by Princess Mary, paid a visit to the Tuberculosis Sanatorium, Papworth Hall, Cambridge, inspecting, as well as the central institution, the workshops where the open-air shelters are being constructed and the cottages in the village which are occupied by ex-patients employed in various ways on the estate. Before leaving the Queen intimated to Colonel Sims Woodhead her intention of sending a contribution of £1000 for the purchase of more cottages. Among those present were the Lord Lieutenant of Cambridgeshire, the High Sheriff, the High Steward, the Mayor, the Acting Vice-Chancellor, Dr. T. N. Keynes (the Registrary of the University), Mr. J. F. P. Rawlinson, M.P. (the Recorder), Sir Clifford Allbutt (Regius professor of physic), and Sir Arthur Newsholme, representing the Local Government Board. The colony, originally started at Bourne in January, 1916, was removed to Papworth Hall in February of the present year, Sir Ernest Cassel having given £5000 towards the expansion of the institution. Property was acquired which extended the estate to nearly 100 acres, and the Ministry of Pensions offered £3000 for a lien on 30 beds during the war and 10 beds for a later period. There are now 50 patients in residence, under the charge of Mr. P. C. Varrier-Jones, honorary resident medical officer, but further extensions in accommodation are to be made in consequence of a gift of £10,000 from the National Relief Fund. A special feature of the colony is its industrial side, the ex-patients carrying on various trades in the open air, and it is hoped that gradually a self-supporting village community may be built up around the central institution. For the completion of the work of the institution already undertaken by the committee £7000 is still required.

DONATIONS AND BEQUESTS.—By the will of the late Mr. Alfred Ridley Bax, F.S.A., the Royal Hospital for Incurables will receive £1000.—The late Major-General William Henry Knight left by will £500 to the Royal Victoria Hospital, Dover.

ANNUAL MEDICAL SERVICE AT LIVERPOOL.—The service was held as usual at the church of St. Luke on Oct. 13th, and was attended by the Lord Mayor (Major J. Utting, R.A.M.C.) in state, Professor W. Thelwall Thomas, President of the Liverpool Medical Institution, and a number of leading medical men. The collection, on behalf of the Royal Medical Benevolent Fund, realised the record amount of £130, a result largely due to the efforts of the Lord Mayor, who collected a considerable amount before the date.

LITERARY INTELLIGENCE.—The Library Press, Ltd., London, hope to publish within a week or two a translation of Professor Jules Amar's book on "The Physiology of Industrial Organisation and the Re-employment of the Disabled." The translation has been made by Mr. Bernard Miall, and has been edited, with notes and an introduction, by Professor A. F. Stanley Kent, M.A., D.Sc. Oxon. We reviewed the French edition of this book in THE LANCET of April 21st, 1917.

NEW CONVALESCENT HOME IN DEVON.—A convalescent home for 20 delicate children was formally opened on Oct. 9th at Dousland. Mrs. Waldorf Astor has provided the home, which stands in pleasant grounds on the borders of Dartmoor. The institution is intended for children from Plymouth, and Mrs. Astor will defray all expenses for the first two or three years. The honorary physician is Dr. John G. Bailey, and the honorary surgeon Mr. George Jackson.

OLD-AGE PENSIONERS AND WORKHOUSE TREATMENT.—The Helston (Cornwall) board of guardians has been informed by the Local Government Board that in the case of old-age pensioners admitted to the workhouse infirmary, if the pension officer was satisfied that this admission was principally due to the need of medical treatment, the pension would be continued, but if the pensioner had become a chronic inmate of the infirmary the question of disqualification could be raised by the Local Pensions Committee.

THE SERVICES.

ARMY MEDICAL SERVICE.

Cols. T. G. Lavie and J. Girvin retire on retired pay.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. S. H. Withers retires on retired pay.

Major (Bt. Lieut.-Col.) B. A. Craig to be acting Lieutenant-Colone whilst in command of a Medical Unit.

Major M. C. Wetherell relinquishes the acting rank of Lieutenant-Colonel on re-posting.

Capt. Sir T. C. English, R.A.M.C. (T.F.) (hon. Col. in Army), to be temporary Lieutenant-Colonel whilst specially employed.

Temp. Capt. (acting Lieut.-Col.) F. W. G. Deane relinquishes his acting rank on ceasing duty at Leith War Hospital.

The undermentioned to be acting Lieutenant-Colonels: Temp. Major (Capt., R.A.M.C. (T.F.)) W. Robertson; whilst in command of a Medical Unit: Capt. (acting Major) S. D. Large, Capt. (acting Major) H. A. Harbison.

Temp. Capts. relinquishing the acting rank of Major: E. W. Craig, W. K. A. Richards; on re-posting: T. E. R. Branch, K. B. Dickson, G. W. Stone.

To be acting Majors: Temp. Major P. Turner; Capt. (Brevet Major) H. F. Panton; Temp. Capts. J. N. Wheeler, G. Jackson, A. L. Krogh, H. V. Leigh, F. P. Joscelyn, R. S. Scott, E. C. Lindsay, T. H. Just, V. F. Soothill, T. A. Lawder, H. F. N. Scott, H. Pringle, A. Manuel, P. Moran; Temp. Lieut. G. B. Warburton. Whilst specially employed: Temp. Capts. R. C. Harkness, J. Donald, J. L. Rankine, C. C. de B. Daly.

F. McE. Sinclair and H. Whitwell, late temporary Captains, are granted the honorary rank of Captain.

R. P. Mitchell to be temporary Honorary Captain whilst serving with British Red Cross Society in France.

Officers relinquishing their commissions: Temp. Major R. O. Moon; Temp. Capts. J. A. A. Orlebar, W. Dickson, E. V. Frederick, H. F. Wickens, F. C. Stewart, R. B. John (on account of ill-health contracted on active service, and is granted the honorary rank of Captain), W. M.

Fergusson (on account of ill-health, and is granted the honorary rank of Captain), W. S. Foote, E. Macmillan, G. A. Barss, C. G. Shearer (on account of ill-health contracted on active service, and is granted the honorary rank of Captain), J. G. Reidy (on account of ill-health contracted on active service, and is granted the honorary rank of Captain); Temp. Hon. Capt. F. W. Goyder (on ceasing to be employed with St. John Ambulance Brigade Hospital); Temp. Lieuts. F. Spearing (on account of ill-health contracted on active service, and is granted the honorary rank of Lieutenant), A. C. Norwich (on account of ill-health caused by wounds, and is granted the honorary rank of Lieutenant), W. S. Gibson (on account of ill-health, and is granted the honorary rank of Lieutenant), C. J. G. Exley (on account of ill-health); Temp. Hon. Lieut. H. E. Durham (having ceased to be employed with Welsh Hospital, Netley).

Canadian Army Medical Corps.

Temporary Captains to be temporary Majors): D. B. Kennedy, J. A. Briggs, H. Hart.

Temp. Capt. J. McCulloch to be acting Major while employed at Canadian Depôt.

Temporary Captains to be acting Majors while employed at a Canadian Field Ambulance: H. M. Barrett, F. W. Lees, E. Douglas, L. C. Palmer.

SPECIAL RESERVE OF OFFICERS.

Capts. M. W. Ruthven and S. J. Steward relinquish the acting rank of Major on re-posting.

Capt. D. M. Marr to be acting Major.

Capt. H. Taylor relinquishes his commission on account of ill-health, and is granted the honorary rank of Lieutenant.

TERRITORIAL FORCE.

Lieut.-Col. O. E. B. Marsh is retired, having attained the age limit, and is granted the honorary rank of Lieutenant-Colonel.

Major J. Allison to be acting Lieutenant-Colonel whilst specially employed.

Major A. V. Ford relinquishes his commission on account of ill-health, and is granted the honorary rank of Major.

Capts. H. E. Gibson (General List) and W. Malden relinquish their commissions on account of ill-health, and are granted the honorary rank of Captain.

Capt. (acting Major) M. U. Wilson (General List) relinquishes his acting rank on ceasing to be specially employed.

Captains to be acting Majors whilst specially employed: W. E. H. Bull, F. J. Green, W. J. Gray, A. R. Muir.

Capts. J. B. Macalpine and W. Gough are restored to the establishment.

Lieuts. L. H. Callendar and C. P. Matthews to be Captains.

TERRITORIAL FORCE RESERVE.

Capts. J. A. Menzies and A. R. Moodie, from R.A.M.C., to be Captains.

ROYAL AIR FORCE.

Medical Branch.—J. Maclaughlin (Lieut.-Col., retired, R.A.M.C.) is granted a temporary commission as Captain and to be honorary Lieutenant-Colonel. H. McWilliam Daniel, M. Murphy, W. Lessey (late Captain, R.A.M.C.) are granted temporary commissions as Captains. F. S. Drewe, A. Henderson, T. Acton, O. Hilton are granted temporary commissions as Lieutenants.

Dental Branch.—R. C. T. Evetts, N. A. Goudge, A. E. F. Peaty, F. J. Bradburn are granted temporary commissions as Lieutenants.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Parliamentary Session.

BOTH Houses of Parliament resumed on Tuesday, Oct. 15th, after a recess extending from the beginning of August.

HOUSE OF COMMONS.

TUESDAY, OCT. 15TH.

The Midwives Bill.

Mr. HAYES FISHER (President of the Local Government Board), in moving the second reading of the Midwives Bill, said that the measure had originally been introduced and passed in the House of Lords. When, however, it came down to the House of Commons a lynx eye discovered that there was a flaw in it. It infringed the privilege of the House of Commons inasmuch as some of its clauses made a charge on public funds. This being the case there were three courses open: first, to reintroduce the Bill in the House of Lords without the offending clauses; secondly, to introduce the Bill into the House of Commons with the clauses which created the charge; and thirdly, to drop the Bill. At that time—late in July—the Chancellor of the Exchequer, who was responsible for the conduct of the business of the House, was beginning the slaughter of the innocents, and there was no time for the Bill to be considered in the House of Commons. Therefore there was only one course to take—namely, to drop the Bill for the time, with the intention of introducing it into the House of Commons at the earliest possible date. The Midwives Act of 1902 only applied to England and Wales, and not to Scotland or Ireland. The two latter countries obtained some advantages in that respect, because a Departmental Committee which was appointed to inquire into the operations of the 1902 Act made certain valuable recommendations regarding amendments which might fittingly be made in the Act. Since Scotland and Ireland had obtained Midwives Acts in which those recommendations were incorporated England and Wales had become the Cinderella of midwives legislation, and the whole object of the present Bill was to assimilate the law relating to midwives, so that the whole legislation on the subject throughout the United Kingdom would be in harmony. Proceeding to mention one or two of the more important clauses, Mr. Hayes Fisher said that Clause 2 made arrangements for a more equitable apportionment regarding any deficit which might accrue to the local authorities. The apportioning of the deficit was made on the basis of the population, and not on the basis of the number of midwives who had taken out certificates. The old apportionment was somewhat cumbersome and inequitable. Those local authorities which were most active in promoting the work of the midwives were to a certain extent penalised by having to take upon themselves a larger proportion of the deficit than they ought to have done. Under Clause 6 compensation was introduced for the first time to women who had been suspended through no fault of their own. Clause 8 provided that a woman struck off the Roll should return her certificate to the Board. By Clause 10 there would be reciprocal recognition of the certificate of the Central Midwives Board not only in the United Kingdom but in the British Dominions, with the proviso that the term of training must be the same in each case. Clause 12 enabled the county council to delegate its duties to the district council except in cases where that power had already been exercised. This was the only clause on which there was division of opinion in the House of Lords, and it was quite possible that division of opinion might manifest itself on that clause in the House of Commons when the Bill went into Committee. Clause 14 made it obligatory to summon a medical man in emergency cases and for the local authority to pay his fee. They would be able to recover 50 per cent. of these fees from grants made by the Treasury under the administration of the Local Government Board. Everyone must be anxious at this time to do all they could in relation to maternity and child welfare. There was a great shortage of midwives at the present time, and if they could do anything to raise their status and remove the difficulties under which they worked they were doing something at all events to diminish the perils of motherhood and to ensure that a better class of woman would take up the ancient and honourable profession of a midwife.

Replying to a number of questions, Mr. HAYES FISHER said that it would be possible to increase the number of women on the Central Midwives Board. It would be possible, if it was found desirable, to give midwives themselves direct representation on that Board. The Government had thought it better to bring in the Bill as it left the House

of Lords, but when they came to Clause 12, which was probably the only one which would excite any debate or division, he would listen with a very open mind to the arguments put forward as to whether or not the delegating of powers should be allowed. But he thought that it would be wise to give a discretionary power to the Local Government Board and not to close the door entirely to delegation and matters of that kind.

The Bill was read a second time.

Appointments.

DEAN, L. T., M.B. Cantab., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Spilsby District of Lincoln.

O'DONNELL, P. C., M.B., B.Ch., Certifying Surgeon under the Factory and Workshop Acts for the Dingle District of the County of Kerry.

Vacancies.

For further information refer to the advertisement columns.

Alnwick Infirmary.—H.S. £150.

Barrow-in-Furness, County Borough.—Female Asst. M.O.H. and Asst. Sch. M.O. £450.

Bradford.—Temp. Asst. Sch. M.O. £8 8s. per week.

Bristol Royal Infirmary.—H.P. and H.S. £120.

Burton-on-Trent Infirmary.—H.S. £200.

Cambridge, Addenbrooke's Hospital.—H.P. £300.

Cambridge Borough Education Committee.—Asst. Sch. M.O. £400.

Chester Royal Infirmary.—H.S. £200.

Chesterfield and North Derbyshire Royal Hospital.—Sen. H.S. £300.

Exminster, Devon Mental Hospital.—L.T. 7 gs. per week.

Grimsby and District Hospital.—Res. H.S. £200.

Hastings, East Sussex Hospital.—H.S. £250.

Huddersfield County Borough.—Female Asst. M.O.H. £400.

Kent, Bromley Union Guardians' Institution, Farnborough.—M.O. £250.

Kirkburton, Storthes Hall Asylum, Huddersfield.—L.T. £7 7s. per wk.

Leicester, Leicestershire County Council Education Committee.—School Dentist, £400.

Manchester, Crossley Sanatorium, Delamere Forest, Cheshire.—Asst. M.O. £300.

Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—H.S. £150.

National Hospital for the Paralysed and Epileptic, Queen-square, W.C.—Res. M.O. Also Jun. H.P.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Asst. Res. M.O. £250. Also H.P.'s. and H.S.'s. £50, and (in one case) £100.

Newcastle-upon-Tyne, University of Durham College of Medicine.—Lect. Psych. Med.

Northampton General Hospital.—Jun. H.S. £150.

Plymouth, South Devon and East Cornwall Hospital.—H.P. £200.

Queen Charlotte's Lying-in Hospital, N.W.—Asst. Res. M.O. £60.

Reading, Royal Berkshire Hospital.—H.S. £250.

Roll of Honour Hospital for Children, 688, Harrow-road, W.—Female Asst. Phys.

Royal Free Hospital, Gray's Inn-road, W.C.—Paths. to Ven Dis. Dept. and to Military Sect. £150. Also Asst. Path. £250.

Royal London Ophthalmic Hospital.—Deputy Bacteriologist. £120.

Salford Royal Hospital.—H.P. £250. H.S. £200. Jun. H.S. £150.

Sheffield City Hospitals.—Asst. M.O.

Shrewsbury, Salop County Asylum.—Temp. Asst. M.O. £300.

South London Hospital for Women.—Female Clin. Asst. £1 1s. per attendance. Also Anæsth. 10s. 6d. per attendance

Wakefield, Clayton Hospital.—H.S. £250.

Winchester, Royal Hampshire County Hospital.—Sen. Res. M.O. £400.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Swaffham, Norfolk, and at Spennymoor, Durham.

Births, Marriages, and Deaths.

BIRTHS.

NEILD.—On July 13th, at 7, Love Lane, Shanghai, the wife of F. M. Neild, M.B., B.S. (Lond.)—a daughter.

RIDDELL.—On Oct. 14th, at Chalmers-street, Edinburgh, the wife of Captain (Acting Major) J. W. G. H. Riddell, M.C., R.A.M.C., T., of a son.

MARRIAGES.

ADDEY—WILSON.—On Oct. 7th, at Shepperton Parish Church, William Fielding Addey, Captain, R.A.M.C., to Edith Jane, daughter of the late James Wilson, of Alford, Aberdeenshire.

STALKER—MACLEAN MANSIE.—On Oct. 12th, at Dundee, Captain J. M. Stalker, R.A.M.C., to Jeannette Maclean Mansie, M.B., Ch.B.

DEATHS.

BIERNACKI.—On Oct. 11th, at the Hospital, John Biernacki, M.B., Physician-Superintendent of Plaistow Fever Hospital, and of 17, Wimpole-street, Cavendish-square.

MCLAGGAN.—Killed in action on Oct. 4th, Captain J. Murray McLaggan, M.C., R.A.M.C., attached Royal Fusiliers, aged 27 years.

PRIESTLEY.—On Sept. 28th, at Salonika, of influenza, Major Percival T. Priestley, R.A.M.C.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.1.

MEETINGS OF SECTIONS.

Tuesday, Oct. 22nd.

MEDICINE
PATHOLOGY
EPIDEMIOLOGY: *Discussion* on "Epidemic Encephalitis," at 5.30 P.M. Speakers: Dr. F. W. Mott, Dr. S. P. James, Dr. A. S. MacNalty, Dr. W. H. Hamer, Dr. A. J. Hall, Dr. P. N. Panton, Dr. F. G. Crookshank, and others.

Wednesday, Oct. 23rd.

SURGERY (Hon. Secretaries—V. Warren Low, Cyril A. R. Nitch): at 6 P.M.
Presidential Address by Sir J. Bland-Sutton: Spolia Opima.

Friday, Oct. 25th.

STUDY OF DISEASE IN CHILDREN (Hon. Secretaries—Eric Pritchard, H. C. Cameron, C. P. Lapage): at 4.30 P.M.
Cases will be shown.
Demonstration: Dr. K. S. Bhat: A New Counting Chamber for Cells, &c., in Fluids.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
FRIDAY, Oct. 25th.—5 P.M., Museum Demonstration:—Prof. A. Keith: The Physiological Effects of Massage and Gymnastics.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Clinics each week-day at 2 P.M., Wednesday, Friday, and Saturday also at 10 A.M.
(Details of Post-Graduate Course were given in issue of Sept. 27th.)

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Out-patients each day at 2.30 P.M.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.
Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—
WEDNESDAY, Oct. 23rd.—4 P.M., Lecture III:—Dr. W. M. Willoughby: The Obviation of Ship-borne Infections.

CHADWICK PUBLIC LECTURES, at the Rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.
Lectures on the Story of a New Disease (illustrated by epidiascope):—
THURSDAY, Oct. 24th.—5 P.M., Lecture III:—Dr. F. G. Crookshank: (1) Raphania; (2) Botulism; (3) Theory of the Heine-Medin Disease.

Communications, Letters, &c., to the Editor have been received from—

A.—Dr. W. H. B. Aikins, Toronto.

B.—Surg.-Gen. R. Blue, Washington; British Hospitals Association, Lond., Hon. Sec. of; Sir John Bland-Sutton, Lond.; Dr. C. H. Bond, Lond.; British Organotherapy Co., Lond.; Mrs. Cloudesley Brereton, Lond.; Dr. T. B. Broadway, Dorchester.

C.—Messrs. J. and A. Churchill, Lond.; Dr. A. B. Carver, Torquay; Rev. Dr. Corner, Abergavenny; Chicago School of Sanitary Instruction; Messrs. Clement and Johnson, Lond.; Dr. F. G. Crookshank, Lond.; Mr. J. Cabburn, Lond.; Miss M. M. Cashmore, Woolwich; Central Midwives Board, Lond., Sec. of; Dr. H. P. Cholmeley, Forest Row.

D.—Mr. S. H. Davey, Neath; Major H. Dutch, R.A.M.C.(T.); Surg. Lt. Comm. S. F. Dudley, R.N.

E.—Dr. W. Ewart, Lond.; Dr. A. D. Edwards, Bournemouth; Eagle, Star and British Dominions Insurance Co., Lond.

F.—Dr. R. Fenner, Lond.; Dr. W. M. Feldman, Lond.; Dr. A. M. Fraser, Portsmouth.

G.—Dr. D. Graham, Boston; Mr. H. J. Gauvain, Alton; Glasgow, Medical Officer of Health of; Miss L. Givens, Sheffield; Sir A. Pearce Gould, K.C.V.O., Lond.; General Medical Council, Lond., Acting Registrar of.

H.—Dr. I. Harris, Liverpool; Dr. J. B. Hurry, Reading; Rev. C. W. Heald, Chale; Dr. R. H. Hann; Major-Gen. Sir W. P. Herringham, C.B.

I.—*The India Rubber Journal*, Lond., Editor of.

J.—Rev. H. B. Jones, Hull; Mrs. J. A. Johnston, Dunbarton; Mr. C. L. Jenkins, Lond.; Mr. W. Jones, Liverpool.

K.—Mr. W. H. Kesteven, Kingston-on-Thames; Mrs. F. A. Keynes, Cambridge; Dr. H. C. Kidd, Bromsgrove.

L.—Dr. C. Lillingston, Peppard Common; Local Government Board, Lond.; London Dermatological Society, Hon. Sec. of.

M.—Ministry of Munitions of War, Lond.; Ministry of Food, Lond.; Sir Henry Morris, Bart., Lond.; Dr. Reginald Morton, Lond.

N.—National Baby Week Council, Lond., Sec. of; National Association for the Prevention of Consumption, Lond.

O.—Sir William Osler, Bart., Oxford.

P.—Major J. Phillips, R.A.M.C.; Capt. H. M. Perry, R.A.M.C.; Practitioner.

R.—Royal Medical Benevolent Fund, Lond., Sec. of; Dr. M. R. Rhodes, Lond.; Royal Albert Institution, Lancaster; Dr. R. R. Rentoul, Liverpool; Royal Microscopical Society, Lond.; Mr. S. H. Rouquette, Lond.

S.—Society of Apothecaries of London, Sec. of; Capt. C. B. Sundell, R.A.M.C.; Capt. J. L. Stoddard, M.C., U.S.A.; St. John's Hospital, Lond.; Dr. E. I. Spriggs, Banff; Dr. W. B. Sansom, Lond.; Dr. E. Stolkind, Lond.; Capt. A. R. Snowdon, R.A.M.C.

U.—University College, Lond., Provost of; University of Cambridge.

W.—Brig.-Gen. F. A. Winter, M.C., U.S.A.; Dr. L. Williams, Lond.; Dr. F. P. Weber, Lond.; Warrington, Medical Officer of Health of; Major R. B. Wild, R.A.M.C.(T.); Dr. F. G. Wallace, Lond.; Dr. J. R. Whitwell, Melton; Messrs. John Weiss and Son, Lond.; Lt.-Col. J. H. T. Walsh, I.M.S. (retd.)

Notes, Short Comments, and Answers to Correspondents.

SOME EARLY BRITISH SURGEONS.

THE fifth volume of the *British Journal of Surgery* (Bristol: John Wright and Sons, Ltd. Pp. 714. Price 36*s.* 6*d.*) contains four articles dealing with one fourteenth century surgeon—namely, John Arderne, and three Tudor surgeons, John Banester, John Halle, and Thomas Vicary. John Banester, like his fellows Halle and Vicary, whose lives are given in the volume before us, and his other contemporaries, Gale, Clowes, and Read, were all Elizabethan surgeons, who strove to raise the status of surgery in England and to restrain quacks. They succeeded in their former effort to a very limited extent, but probably were not successful in the latter, although severe measures had been taken by the Act of 1531 against vagabondage, including "rogues who pretended to a knowledge of physic." Banester acted as surgeon to the Forces sent to relieve Havre in 1563, and in 1572 he was admitted a Member of the Barber Surgeons Company, apparently more owing to interest than to his undoubted merits. A note in the records of the Company says:—

"Mr. Banester, of Nottingham, was sworn and admitted a brother of this mystery. Whereupon he hath granted to the House yearly twenty shillings so long as he liveth, and to be liberal and commodious to this house in that he may and will yearly send a buck or two, and hath paid ten shillings and shall have his licence."

His biographer suggests that Banester's friendship with Clowes or his own family interest may have gained him admission to the Company, but we expect that the 20*s.* and the promise of the bucks had something to do with it too. In 1573 the University of Oxford granted him a licence in medicine, and in 1593 he received the licence of the Royal College of Physicians of London by desire of Queen Elizabeth. He was the Company's "Visceral Lecturer" in 1581, and an interesting picture (reproduced in the book) is extant of the proceedings at the lecture. From this picture we can get a very accurate idea of a demonstration in anatomy of the sixteenth century. It is pleasant to find from the records of the Company that provision was made for all things to be done decently and in order. Thus, the body was to be kept behind curtains until it "is wrought upon" (i.e., by the "Masters" or "stewards" of anatomy, who were apparently what are now called prosectors). The dissection being finished, all was to be made clean "and covered with fayre clothes" until the doctor should come to demonstrate. Both the doctor and the stewards were to have clean aprons and sleeves every day, and the latter were to see that all their instruments were clean. Banester died in 1610, so that at the date of this picture (1581) he was 48, having been born in 1533.

John Halle (1529–1568) was born in Maidstone. Little is known of him except from his books. Among these were a translation of Lanfranc's "Surgery" with a glossary, in which, concerning the word "algebra" we think he has made an error. He says:—

"The Arabye word 'algebra' signifieth as well fractures of bones, &c., as sometime the restauration of the same."

We do not think that the word "algebra" ever meant fracture, but was always used of bone-setting—i.e., restoration of fractures. "Algebra" is still used in Spanish to signify bone-setting, and the original Arabic word "al-jebr" means the reunion of broken parts. Halle also wrote a treatise against quacks in the vigorous English of his time, though not a whit too strong for the offences of "the beastly beguilers."

Thomas Vicary (1490–1562) was the leader of the band of Tudor surgical reformers. He was governor of St. Bartholomew's Hospital in 1548, with three surgeons under him. He is best known as the editor or author of a treatise on anatomy generally called "The Englishman's Treasure." The late Dr. J. F. Payne showed conclusively that this work is really an abridgment of a fourteenth century derivative of Lanfranc and Mondeville. It is not certain that Vicary claimed to be the author, and probably he simply edited the unknown fourteenth century author, just as Halle did Lanfranc.

John Arderne (1307–1380?) was the first English surgeon of whom we have any detailed knowledge. His chief work was a treatise on fistula in ano and its cure. His treatment was to make a clean incision instead of slowly cutting through the fistula with a ligature. The work has been admirably edited by Mr. D'Arcy Power for the Early English Text Society, Orig. Series 139, 1910.

The modern methods of surgery recorded in the *British Journal of Surgery*, especially the plastic variety, are so astounding that if their exponents had lived at the date of the surgery mentioned above they would have been burned as professors of diabolic arts.

ANTHROPOMETRY AND NATIONAL HEALTH.

THE first of a series of lectures on Public Health Problems under War and after War Conditions was delivered at the Royal Institute of Public Health on Oct. 9th by Professor Arthur Keith, F.R.S., his subject being Anthropometry and National Health. The chair was occupied by Major Leonard Darwin. Professor Keith said he did not believe the Prime Minister had done any greater service than when he drew attention in his speech at Manchester, on Sept. 12th, to the fact that if the health of the people had been looked after we should have been able to put into the fighting ranks at least a million more men, and the war would by that date have ended triumphantly. The first movement in this country to ascertain the physical condition of the people was made by a committee of the British Association in 1875, which in 10 years took measurements of 80,000 men, women, and children. After the Boer War General Maurice (Sir Frederick Maurice's father) stated, in an article in the *Contemporary Review*, that out of every five men who presented themselves for acceptance as soldiers only two were found fit to bear arms. A surgeon-general of the time, after investigating the recruiting statistics for 10 years, said they showed that of every 1000 men who applied to become soldiers 400 had to be rejected. On the initiative of General Maurice the Government appointed a departmental committee, which, after an eight months' inquiry, made a valuable report which recommended the setting up of machinery for investigation, but the report had been pigeon-holed. Conscription, however, had now placed us in possession of the figures in regard to the physical condition of the people. A population which deserved the term "healthy" ought to yield the following per 1000 men: 700 Grade I., 200 Grade II., 75 Grade III. (for sedentary work), and only 25 physically incapable. Yet a midland manufacturing town produced only 200 Grade I., 250 Grade II., 450 Grade III., 100 Grade IV. And that was characteristic of many towns in the Midland and Northern Counties of England and in the South of Scotland. Mr. Lloyd George's statement was found to be well within the mark. That was also true of the Premier's remark that the chief cause of the deterioration was in the home. Dr. A. Shadwell had traversed that statement on the subject in his *Times* letter, but Mr. Lloyd George evidently meant that no first-rate country had done less than England in providing certain conditions for improving the home. Professor Keith said he wanted to see a physical census of the people, and even after the setting up of a Ministry of National Health he would retain the Ministry of National Service, and he would have each county subdivided into areas, so that prevailing standards and ailments could be traced and investigated.

INFORMATION FOR INVALIDED CANADIAN SOLDIERS AND SAILORS.

A NEW version of a familiar poster has been prepared and will shortly make its appearance in Canada, entitled "What Every Invalided Canadian Soldier and Sailor Should Know." The information appearing on it is reproduced in pocket size on a khaki card, which is given to every wounded or otherwise invalided member of the force. The card consists of 26 paragraphs printed in red and black alternately, of which the following are examples:—

1. That his first business is to get well and stay well.
5. That until his discharge, being still a soldier, he is under the care of the Militia Department.
6. That the Department of Soldiers' Civil Re-establishment coöperates by arranging helpful and interesting occupations in the hospitals of the Militia Department.
13. That if he is willing to learn, and takes the opportunities offered him to increase his skill, he can usually get a better position than he had before.
15. That if his service disability prevents him from returning to his old work, after discharge, the Department of Soldiers' Civil Re-establishment gives him free training for a new occupation.
16. That his maintenance and that of his family are paid for as long as this training lasts, and for a month longer if necessary.
21. That a pension, being for disability caused or aggravated by service, cannot be reduced by his taking work or perfecting himself in an industry.
22. That if he needs an artificial limb or other orthopædic appliance it will be supplied free and kept in repair by the Department of Soldiers' Civil Re-establishment.
26. That if he wishes further information, advice, or help from the Department of Soldiers' Civil Re-establishment he should write to its headquarters, 22, Victoria-street, Ottawa, or speak to a representative of the Department. Every man is interviewed by such a representative before discharge.

The number of men accepted for training has now risen to nearly 3000. The motto of the organisation would appear to be Paragraph 12: "Skill won makes up for strength lost."

THE King has given permission to Dr. Lilian Violet Cooper to wear the Insignia of the Fourth Class of the Order of St. Sava, conferred upon her by the King of Serbia in recognition of services as surgeon at the Scottish Women's Hospital at Ostrovo during the present war.

The Harveian Oration

ON

THE DOCTRINE OF CONSUMPTION IN HARVEY'S TIME AND TO-DAY.

Delivered before the Royal College of Physicians of London on Oct. 18th, 1918,

BY PERCY KIDD, M.D.OXON., F.R.C.P. LOND.,
PHYSICIAN, LONDON HOSPITAL; CONSULTING PHYSICIAN, HOSPITAL FOR CONSUMPTION AND DISEASES OF CHEST, BROMPTON, ETC.

MR. PRESIDENT, FELLOWS OF THE COLLEGE, AND GUESTS,—Rather more than 300 years ago, in his Lumleian Lectures delivered in 1616, William Harvey first made known the results of his experiments on the circulation of the blood, though his complete work was not given to the world until 1628. The story of his great discovery has often been told, and well told. I shall not attempt to emulate the felicitous language of my predecessors. Much has been written about Harvey's life and work, perhaps more still remains to be discovered. But success in this kind of research is not given to everyone. If I had felt that it would be my duty on this occasion to attempt to add another stone to the already imposing cairn erected to Harvey's memory, I should not stand here to-day.

In 1656, the year before his own death, Harvey made provision for the annual delivery of an oration to commemorate the benefactors of the College, to exhort the Fellows and Members of the College to search out the secrets of nature by way of experiment, and to continue in mutual love and affection amongst themselves.

This year we have no bequests to record. In previous orations grateful mention has been made of the many benefactions which have been received, and the College has ever been mindful of generous donors.

HARVEY AND THE VALUE OF RESEARCH.

In his injunction to the Fellows and Members of the College to search out the secrets of nature by way of experiment, Harvey urges others to follow the practice which, in his hands, had led to such great results. His discovery of the circulation of the blood was founded on experiment and could not have been worked out in any other way. While learned physicians were engaged in subtle metaphysical discussions about disease, Harvey addressed himself to his own experimental work until he felt justified in publishing his revolutionary results.

In his introduction to the "Treatise on the Generation of Animals" Harvey pours contempt on the exclusive reference in all discussion to the authority of the great men of the past in these words:—

> "The method of investigating truth commonly pursued at this time therefore is to be held as erroneous and almost foolish, in which so many inquire what others have said, and omit to ask whether the things themselves be actually so or not."

Yet Harvey was no despiser of the Ancients, as his numerous references to Aristotle and Galen attest.

At the present day there is no fear of undue respect being paid to the Old Masters; nay, the young lions of the twentieth century are too well satisfied with their own prowess to devote much thought to an ignorant age that knew nothing of vaccines, blood cultures, test meals, blood counts, and other revelations of these latter days.

In this crisis of our history, when all men's thoughts are directed to the life-and-death struggle which our country is waging in defence of the liberties of the world against the sinister forces of reaction, let us recall the period of Harvey's lifetime that immediately followed the execution of Charles the First.

At this troublous and disturbed time Harvey had retired from London, and the following account of a visit paid to him in his retirement by Ent has a special interest for us to-day. In his introduction to Harvey's "Anatomical Exercises on the Generation of Animals," published in 1651, Ent thus addresses "the learned and illustrious the President and Fellows of the College of Physicians of London":—

> "Harassed with anxious and in the end not much availing cares, about Christmas last (the year after the violent death of the King.—Ed.) I sought to rid my spirit of the cloud that oppressed it by a visit to that great man, the chief honour and ornament of our College, Dr. William Harvey, then dwelling not far from the city: I found him, Democritus-like, busy with the study of natural things, his countenance cheerful, his mind serene, embracing all within its sphere.
>
> I forthwith saluted him and asked if all were well with him.
>
> 'How can it,' said he, 'whilst the Commonwealth is full of distractions, and I myself am still in the open sea? And truly,' he continued, 'did I not find solace in my studies, and a balm for my spirit in the memory of my observations of former years I should feel little desire for longer life? But so it has been, that this life of obscurity, this vacation from public business, which causes tedium and disgust to so many, has proved a sovereign remedy to me.'"

We may feel sure that had Harvey lived in these days, when not only the Commonwealth of England but the whole world is full of distractions, he would still have found solace in his studies. What Harvey did we may all do according to our several capacities. Those of us who, from one cause or another, are unable to render direct service to the State can yet help to carry on the civil life of the community which is indispensable to the successful conduct of one of the most righteous wars in which our country has ever been engaged.

It is hardly necessary at the present day to insist on the value of experiment in the elucidation of disease, and Harvey's injunction to search out the secrets of nature by way of experiments has now lost something of its original point. To-day experiment is in the air. And though much of the laboratory work published appears sterile and inconclusive, all additions to the sum of knowledge, however small and indirect, must have their value. In no disease, perhaps, has the beneficent influence of experiment been more strikingly exemplified than in consumption or tuberculosis. Experiment has been the light that lightened our darkness.

The seventeenth century, with its many wonderful achievements in literature, art, and science, marks the beginning of a new era in the study of consumption. Let us, then, compare the doctrine of consumption in Harvey's time with that of to-day.

FROM HIPPOCRATES TO THE SEVENTEENTH CENTURY.

In order to comprehend the state of opinion in Harvey's time we must retrace our steps to the time of Hippocrates, to whom we owe the first recorded account of consumption.

Hippocrates defines phthisis as suppuration and ulceration of the lung, and includes under the same head empyema, abscess of the lung, and gangrene. He speaks also of φυματα, swellings or growths in the lung, as causing phthisis. In Latin editions of his works these are translated "tubercula," hence, as Waldenburg points out, it has been thought that Hippocrates was acquainted with tubercles. But Virchow, after a critical examination of the passages in which φυματα are mentioned, came to the conclusion that these were circumscribed abscesses and not tubercles in the modern sense. These swellings are attributed by Hippocrates to collections of mucus or bile which suppurate, and are described as occurring also in the tonsils and in other parts.

The causes of consumption are pneumonia which fails to resolve in a critical manner, spitting of blood, and suppuration in the pleura. Pituitous secretion dropping down from the head and stagnating in the lung is another cause of suppuration and phthisis.

It is an eloquent testimony to the authority of Hippocrates that these views were adopted wholly or in part by every writer of note for the next 2000 years. Celsus added nothing to the account given by Hippocrates. Aretæus was the first to distinguish phthisis from empyema. Hear what he says:—

> "If an ulcer form in the lungs from an abscess or from a chronic cough or from the rejection of blood, and if the patient spit up pus, the disease is called Pyeor Phthisis. But if matter form in the chest or side or be brought up by the lungs the name is Empyema; but if in addition to these symptoms the lung contract an ulcer, being corroded by the pus passing through it, the disease no longer gets the name of Empyema, but takes that of Phthoe instead of it."

Aretæus makes no mention of φυματα or anything resembling tubercles in the lungs.

Galen in the main follows Hippocrates.

Phthisis is caused by ulceration of the lung. Ulcers of the lung are like ulcers of any other parts, and are due to direct injury, rupture and hæmorrhage from strain, and inflammation. Galen speaks of φυματα as inflammatory swellings resembling furuncles and buboes. One of the earliest references to contagion is believed to be found in these words:—

> "It is dangerous to live with consumptives and with those whose foul breath imparts a heavy odour to the rooms in which they lie."

Bulloch and Greenwood point out that Aristotle had expressed similar views concerning contagion.

The Arabian physicians closely followed Hippocrates and Galen, and made no further contribution to the subject. Phthisis remained an ulcer of the lung. The position was unchanged until the seventeenth century.

At this eventful period, when anatomical examination of the dead became more general, medical science began to burst its fetters, and a true renascence of medicine set in. The time which produced Harvey's great work on the Circulation witnessed other striking developments of medical knowledge, and this century constitutes one of the great epochs in the study of consumption. Among the writers of this time who dealt with this disease two men stand out pre-eminently, Franciscus Sylvius and Richard Morton.

Some account of the life and work of these two great men will, I hope, prove not uninteresting.

FRANCISCUS SYLVIUS (1614–1672).

Franciscus de le Boë Sylvius (not to be confounded with Jacobus Sylvius, who lived about one hundred years earlier) was born in 1614 at Hanau, in Germany.

His family was French, by name Du Bois or De le Boë, but his grandfather François, a Huguenot, had migrated to Germany to escape the religious persecutions of the time. The family had a distinguished military record, but owing to pecuniary losses François had embarked in commerce, for which Germany at that time offered favourable opportunities, having enjoyed peace for a considerable time. Isaac de le Boë, the son of François, married Anna de la Vignette, whose family came from Cambrai. Their son, afterwards known as Sylvius, was named François.

Lucas Schacht says that the boy's "beauty" of person, bodily activity, and gentle and virtuous disposition, inspired his father with the hope that such a body could only be inhabited by a lofty mind. His father determined, therefore, to give him a good education, and François was sent to Sedan to be instructed by learned and religious men in a Protestant school. Sedan, as Jelliffe points out, was one of the cities of refuge on the French border where Huguenots were tolerated.

The Medical Career of Sylvius.

When his schooling was completed he was given his choice of a profession: commerce, military science, or letters. He chose the last, and expressed a desire to study medicine. This decision met with his father's warm approval, and François returned to Sedan to study philosophy and medicine. After two years he went to Germany and the Netherlands to complete his education. At the age of 23 he was admitted Doctor of Medicine at Basle in 1637, and received authority to teach and practise medicine. After this time he assumed the Latin name of Sylvius. At his parents' desire he returned to practise at Hanau, his native town. But two years later he set out again to prosecute his studies in France and the Netherlands, finally settling at Leyden. Here he opened a school of anatomy and practised medicine with great success. His anatomical teaching became so celebrated that students were attracted to him from all parts. Anatomy and chemistry were the subjects to which he specially devoted himself. So great was his fame as a teacher of anatomy, says Lucas Schacht, that anyone who had not worked under him was thought to know little of the subject.

A few years later, to the surprise of his friends and to the grief of his pupils, he migrated to Amsterdam, when he was 27–28 years of age. Soon after his arrival he was appointed by the deacons of the Walloon Calvinistic Church to the care of their sick poor.

> "This charge," says Jelliffe, "without pay, gave him the public confidence, and at the same time facilitated his clinical researches."

The reputation which he brought with him from Leyden was speedily confirmed, and before long he obtained the chief practice in Amsterdam. He was beloved by the poor, whom he supplied gratuitously with costly drugs, many of them prepared with his own hand. His diligence, pity, civility, gentle manners, and sobriety commended him to all.

> "Who," says Schacht, "ever saw Sylvius drunk or disgraced by drink, a fault, alas! too common among medical men?"

In 1658 he was elected professor of medicine at Leyden, and for the next 14 years his activity in teaching, research, and clinical teaching was amazing. Opportunities for clinical teaching were provided by a small infirmary with 12 beds at Leyden, and these were very successfully developed by Sylvius. But Jelliffe shows that it is not correct to say, as some have done, that Sylvius was the first to give bedside instruction, for this method of teaching was originally employed at Padua in 1558, and had been imported into Leyden early in the seventeenth century, where it continued to be carried on for some years, though in a desultory fashion.

Sylvius had a most inspiring influence on his students; so many of whom achieved distinction afterwards that, in the words of Lucas Schacht—

> "The learned men that came from his school rivalled in numbers the crowd of warriors that sprang from the Trojan horse."

In 1668 his second wife and his only child succumbed to an epidemic fever, and Sylvius himself narrowly escaped the same fate in the following year. But on Nov. 14th, 1672, a second attack of the same disease carried him off in his fifty-eighth year. Jelliffe suggests that this epidemic disease was typhoid fever, but the fact that Sylvius had two attacks of the same nature in four years throws some doubt on this.

Sylvius's Contributions to Medicine.

Frank Baker, of Washington, in a very careful study of the anatomical works of Sylvius, comes to the conclusion that he was not the first to describe the Sylvian aqueduct, which was known to anatomists before his time or that of Jacobus Sylvius, who has also been credited with the same discovery. But from the evidence of his contemporary, Thomas Bartholinus, and of later writers, Franciscus Sylvius seems to have been the first to describe the Sylvian fissure.

Portal says that, though he worked much at anatomy, Sylvius made no great advance in this science. But Baker states that he invented a system of sections of the brain in different directions by which structures could be more effectively displayed. In addition he made examinations of lymphatic vessels, salivary glands, pancreas, and the spleen. He pointed out the difference between ductless glands, which he named conglobate, and acinous glands, called by him conglomerate. He believed that the ductless glands had a profound influence on the blood, and he thus may be said to have been in a sense a forerunner of modern views concerning internal secretions.

Portal points out that Sylvius had some knowledge of chemistry and its application to the human body. He was one of the early advocates of the fermentation of humours, which he applied to the explanation of secretions. He regarded the pancreatic juice as acid and the bile as alkaline; the contact of acid and alkali in the intestine gave rise to a new juice which preserved the balance between the acid and alkali. He was the author of numerous other explanations. With such principles, Portal says:—

> "He did little to advance the history of disease. His labours would have been more profitable if he had imported into his observation and experiments more of the scientific spirit, and if he had preferred description to ratiocination, which beguiles but often deceives us."

This criticism, though sound enough, seems rather severe when we remember the state of physiological knowledge at that time. But Portal, anxious to do him justice, adds in a subsequent passage that Sylvius was more instructed in mechanics than his predecessors, and described correctly the action of the diaphragm, proving that this muscle becomes flattened during inspiration and arched during expiration. He also admits that he made important observations on phthisis based on numerous autopsies. Further, to his credit it must be remembered that he was one of the first to repeat Harvey's experiments and to adopt his views on the circulation.

Eloy, after an adverse criticism of Sylvius's chemical theories, says of him:—

> "But he supported a better cause by defending with all his power the discovery of the circulation of the blood by the celebrated Harvey. Truth is sometimes regarded as a paradox by prejudiced minds, and this discovery, announced by the English physician in 1628, was still rejected as a chimerical fancy by most of the professors of Europe when Sylvius assumed the Chair of Medicine at Leyden in 1658.
>
> The proofs which he collected in favour of Harvey's discovery were so convincing that he had the glory of being the first to teach and demonstrate the truth of these views in the University of Leyden."

Lucas Schacht in his Funeral Oration says that Sylvius having convinced himself of the truth of Harvey's doctrine defended and advocated it publicly with such force that "one might doubt whether the greater honour and praise were due to Harvey, its author, or to Sylvius who first introduced it, published it abroad, and demonstrated its truth in this illustrious academy."

A glance at the medical works of Sylvius will show how wide was the range of his studies. There were few branches of medicine that he did not touch. Apart from his anatomical work, Sylvius has been chiefly known as the author of a purely chemical theory of disease which had little permanence. Nevertheless, these views possess a special interest at the present time, when the importance of physiological and pathological chemistry is so fully realised. But in his work on consumption he stands out as one of the

pioneers of the seventeenth century, and for this reason alone he would merit imperishable renown.

Views of Sylvius on Consumption.

The views of Sylvius on this subject do not appear to have attracted the attention which they deserve; I venture, therefore, to give a somewhat detailed account of them.

In his "Practice of Medicine" he introduces the subject by some general remarks on the nutrition of the lungs.

The lungs waste through the presence of pus, or of blood effused into their substance, or through some fault of their own. The fault lies in the blood when it suppurates, or when an abscess is formed in the course of pleurisy which conveys pus to the lungs either directly or through the blood. Whence not only are the lungs themselves wasted, but the whole body suffers also. The fault lies with the lungs when from any external or internal cause they become incapable of assimilating the blood brought to them, the usual internal cause being an ulcer, the external cause an empyema.

In phthisis not only are the lungs damaged, but the whole body is wasted, inasmuch as the blood is tainted by the intrusion of pus, which infects gradually all parts of the body and renders the processes of nutrition ineffective. The same results, both local and general, may be brought about by the blood containing morbid humours. In this case, whether from an excess of bile, pancreatic juice, or saliva, or from all three, from chyle or lymph vitiated in any way, from serum not being secreted in the kidney and remaining in the blood, or from many other causes affecting the blood, tubercles frequently originate in the lungs, together with textural changes in their soft and spongy tissues.

In the Appendix to his "Practice of Medicine," a posthumous work, he develops his views still further. Not every wasting of the body, but only that which follows an ulcer of the lung, is to be called phthisis.

In addition to the general wasting of the body, other peculiar symptoms are observed in phthisis—a cough and spitting of pus, together with a hectic fever.

Phthisis may be primary when pus is generated in the lung itself or secondary when pus is introduced into the lung from without, the pus infecting and tainting the lung and thus leading to ulceration.

The causes of primary disease of the lung leading to phthisis are numerous, the proximate one being a perforation of blood-vessels, whether by a wound, stab, blow, rupture, fall, shouting, coughing, straining, erosion by acrid humours, or by diapedesis, or exudation through distension or slackness of vessels, or in any other way. In a subsequent passage he says that the proximate cause of phthisis is a persistent ulcer of the lung associated with low fever and wasting. Among the causes of ulcer of the lung, the first place is given to peripneumonia passing into an abscess or vomica, the second to neglected spitting of blood. The other causes include acrid, salt, acid or pituitous humours dropping down from the head into the trachea and ulcerating the lungs, acrid pus penetrating the lungs from the chest walls or from an empyema. But when the aforesaid causes take effect on the lungs previously damaged in their natural constitution and inclined to phthisis, that disease is the more easily and rapidly induced.

"Seeing that experience shows that whole families are so disposed to consumption, that few of their members escape this fell disease, it may justly be asked in what does this phthisical constitution consist? It is notorious that the complaint is hereditary, and passes from parents to children, but the nature of this disposition is not so well understood."

In another passage referring to abnormal formations of the thorax, whether congenital or acquired, and to the hereditary disposition to phthisis, he says that in order to understand this we must believe that the individual humours of the human body change gradually from day to day, and with the progress of years undergo very considerable alterations, also that the solid tissues of the body, including the viscera, are subject to important changes at different age-periods. These changes are most conspicuous in the various glands, some of which wax, while others wane, from day to day. Thus the thymus gland, so large in the fœtus, shrinks greatly in adult life.

"A study of phthisis shows that the lungs possess a peculiar constitution which changes with age, although, so far, it is not possible to describe this accurately or to explain its nature. But this constitution must imply a special susceptibility to the influence of the humours predominating at any particular period of life. This disposition is to be attributed less to the solids than to the fluids of the body. In proportion as individual humours become more or more less acrid at different ages, a varying tendency to disease is manifested. The chief explanation of phthisis attacking persons otherwise in good health without obvious cause is to be looked for in the manifold changes which take place in the humours of the body."

In a subsequent passage he says:—

"I have often found two glands called thyroid lying close beside the trachea which have a certain affinity with the parenchyma of the testes. I suspect that from these a certain juice is poured into the trachea which if preternaturally acid would easily affect the lungs. Changes in this juice at different periods of life may lead to phthisis, especially where there is an hereditary taint."

After recounting the causes of phthisis, which for him means an ulcer or vomica in the lung, he breaks new ground in the following important passage:—

"I will now candidly state what I have observed and what, in my opinion, a vomica is. I have often seen glandular tubercles, both large and small, in the lungs which contained pus. These tubercles being gradually transformed into pus and enclosed in a delicate capsule must, in my opinion, be regarded as vomicæ, and I have frequently seen phthisis originate in these structures. I do not hesitate to ascribe to these tubercles the hereditary and deadly disposition to phthisis exhibited in certain families, for tubercles increase in size in the course of time and pass into suppuration. From my observations I have formed certain conjectures concerning glands which in the natural state are so small as to be invisible, but when diseased become enlarged, and are then seen scattered throughout the viscera and tissues of the body.

These views were suggested by:—

1. The glands of the choroid plexus invisible except in morbid conditions when they may reach a considerable size.
2. The pulmonary glands or glandular tubercles.
3. The glands seen in various parts of the body in the strumous or scrofulous constitution, these glands being of the conglobate variety."

"Inasmuch as we have seen that the small glands of the lungs may swell and become visible in disease and give rise to vomicæ, I suspect that an hereditary disposition to phthisis exists in these bodies."

"In addition to the causes already given, medical writers speak of contagion, the air expired by phthisical subjects being inspired through the mouth and nose of those around and infecting them with its acrid and fœtid miasma, with the result that they ultimately drift into a similar disease. And if we consult our experience and observe accurately what is apt to happen to the more delicate and younger blood relations in immediate contact with the disease, we find that this is only too true.

Wherefore physicians properly warn such persons and particularly close relations to avoid catching the breath of phthisical subjects. The special liability of relations is to be found in the small glands of the lungs invisible under ordinary conditions, but when occupied by a mere viscid humour growing to such a size that they can be seen and felt."

Advances made by Sylvius.

We see from a study of Sylvius's writings how greatly he was dominated by the influence of Hippocrates. "Phthisis sive ulcus pulmonum" is a phrase he uses more than once. Like all previous writers, he attributes phthisis in most cases to peripneumonia or pleurisy, ending in suppuration. But he makes a great advance when he states that tubercles are often seen in the lung in cases of consumption. Still more important is his discovery that tubercles soften and suppurate to form vomicæ. In his view tubercles were nothing more than enlarged glands which he supposed to exist in the lungs and other parts of the body, the enlargement being due to accumulation of viscid humours or secretions in these glands. The origin of the humours is referred to many causes acting for the most part through the blood, especially to excess of various secretions, such as bile, pancreatic juice, or saliva, also to changes in the thyroid secretion, which, as he supposed, found its way into the trachea.

In his conjectures concerning glands which in the natural state are so small as to be invisible, but when diseased become enlarged and are then seen scattered throughout the viscera and tissues of the body, it is not improbable that he is describing cases of generalised miliary tuberculosis. The assumed glandular origin of tubercles in the lungs suggested a relation to scrofula or struma in which external glands were enlarged. The action of heredity is exerted through these glandular tubercles.

Varying conditions of humours, or, as we should say, secretions, at different ages are credited with powerful predisposing influence in the causation of phthisis. May there not be some truth in this? The varying activity and mutual relations of internal secretions, about which, as yet, we possess little accurate knowledge, have profound effects on the human organism, and who shall say that susceptibility to tuberculosis is not in some degree connected with these influences? The phthisical constitution or disposition is also attributed to changes in the humours or secretions of the body.

It seems, then, from the many-sided activities of Sylvius and from his important work on consumption that Baker is justified in describing him as one of the great original thinkers of the seventeenth century, of the period that produced Harvey, Descartes, Leibnitz, and Malpighi.

RICHARD MORTON (*c.* 1635–1698).

Richard Morton was born about 1635, the son of Robert Morton, minister of Bewdley Chapel, in Worcestershire.

According to Copinger, he was born in Suffolk. But in the "Dictionary of National Biography" it is stated that he was baptised at Ribbesford, the parish to which Bewdley belonged, on July 30th, 1637. He matriculated at Magdalen Hall, Oxford, in 1653-54, but migrated to New College, where he subsequently became chaplain, proceeding to the degree of B.A. in 1656-57, and M.A. in 1659. After this he was chaplain to Philip Foley, of Prestwood, in Staffordshire, who appointed him to the living of Kinver, in the same county. Having refused to sign the Act of Uniformity at the Restoration, he was ejected from his living in 1662.

He then turned his attention to medicine. The next thing we hear of him is that he was admitted to the degree of Doctor of Medicine on the nomination of the Prince of Orange in 1670.

I have been unable to obtain any information about his life between 1662 when he was ejected from his living, and 1670, when he received his degree in Medicine at Oxford. The Rev. Claude Jenkins, librarian at Lambeth Palace Library, has very kindly examined the Archbishop's Register and Subscription Book there, but he has been unable to find any record of Morton having received a licence to practise medicine from the Archbishop. Wood says that he was admitted M.D. Oxford in 1670, in which year he accompanied the Prince of Orange to Oxford as physician to his person. Mr. Jenkins suggests that he may have come over from Holland with the Prince after studying medicine at Leyden or Utrecht. I have examined Peacock's Index to English-speaking students who have graduated at Leyden University and the Album Studiosorum Academiæ Rheno-Trajectinæ, but I cannot discover any mention of Richard Morton.

It is strange that nothing should be known about the medical education of a man who afterwards became so famous.

Bishop Burnet in his history tells us that the Prince of Orange came to England in the winter of 1669 in the twentieth year of his age, about a debt owed to his house by Charles the Second. Charles seems to have given the Prince many promises to pay, but little else. That the association between Morton and the Prince was of a satisfactory nature is evident from the fact that the latter after his accession to the throne of England as William the Third appointed Morton one of his physicians-in-ordinary.

After graduating in Medicine at Oxford, Morton came to London and was admitted a Fellow of this College in 1679. He was Censor in 1690, 1691, 1697. In 1680 he was incorporated at Cambridge on his Doctor's degree. He lived in Greyfriars' Court, Newgate-street, where he practised medicine with great success. He died in August, 1698, and was buried in Christ Church, Newgate-street.

Morton's Views on Consumption.

Richard Morton was the author of two works, "Puretologia" and "Phthisiologia," of which the latter alone concerns us now. He defines a consumption of the lungs as

> "An universal wasting of the parts of the body caused by some distemper of the lungs, as a stuffing, swelling inflammation and ex-ulceration of them, and thereupon it is attended with a cough, difficulty of breathing, and other symptoms of the breast, and accompanied with a fever, which at first is slow and hectical, afterwards inflammatory, and at last putrid and intermitting."

> "The cause of a consumption of the lungs in general is a vitiated disposition of the mass of blood, and of the spirits of the nerves contracted gradually from several procatartic or predisposing causes in which the sharp or malignant serum or water of the blood being separated by the soft and glandulous substance of the lungs does stuff, inflame, and at length also ex-ulcerate the lungs themselves, which is the immediate cause of this distemper."

The procatartic or predisposing causes are numerous, and include stoppage of evacuations, passions of the mind, intemperance in eating and drinking, want of exercise, night studies and long watchings, sleeping in the day, an ill air, an hereditary disposition, an ill formation of the breast, infection, chalky stones and such-like in the lungs, or some preceding distemper.

The more immediate cause is a taking of cold. Speaking of infection he says:—

> "This distemper, as I have observed by frequent experience, like a contagious fever does infect those that lie with the sick person with a certain taint."

> "The degrees of this distemper are those which follow, to wit, first a stuffing of the lungs from the serum or water of the blood that is plentifully separated in them. Secondly, a hard swelling, but more especially in the glandulous parts of the lungs, arising from the same serum, distending those parts too much, and not having a free passage out of them: which tumour I take to be the crude tubercle mentioned by Galen; which tubercles, or crude and glandulous swellings I have often found in the dead bodies of consumptive persons, when the other parts of the lungs have been full of apostemes and ulcers. Thirdly, an inflammation of the lungs, arising from the heat and sharpness of this serum. And lastly, an imposthumation and ex-ulceration of these inflamed parts when the distemper comes once to its height and extremity."

Morton here clearly states his opinion that the formation of tubercles constitutes the first stage in the phthisical process. The origin of tubercles is treated as follows:—

> "If anyone shall be inquisitive about the original of the tubercles in the lungs, I shall give this general answer: that the substance of the lungs not only seems more obnoxious to a flux of humours than any other part of the body from the continual motion of these parts caused in respiration, but also by reason of its spongy softness (because it consists wholly of small bladders and vessels) is wont to suck in and retain the humours. ..... When I consider with myself, how often in one year there is cause enough ministred for producing these swellings, even to those who are wont to observe the strictest rules of living, I cannot sufficiently admire that anyone, at least after he comes to the flower of his youth, can die without a touch of consumption.
>
> And without doubt the breeding of these swellings is so frequent and common that a consumption of the lungs would necessarily be the common plague of mankind, if these swellings did not vanish, or were removed by art, as easily as they are bred at first; and indeed I have been used to think, not without reason, that as the more benign tubercles are wont to go off of their own accord, and that quickly, so none of them lay the foundation of the great disease of which I am treating, but only those which are in some degree malignant and ill-natured and that are wont to putrefy sooner or later from some peculiar quality of their nature."

Morton's belief in the great prevalence of tubercle and in the frequency with which spontaneous healing takes place has received striking confirmation in recent times.

> "The crude tubercles resulting from obstruction of the glandulous parts of the lungs undergo a further change. Stagnation of the humours in these glands, caused by the thick glutinous quality of the juice secreted by the glands, leads to a transformation of the tubercle into a dry matter like suet or honey. Inflammation and suppuration follow. Pneumonia or pleurisy, if improperly treated, may end in consumption through the formation of tubercles and abscesses."
>
> "Where a spitting of blood has preceded, a consumption of the lungs is wont to follow." But in this case, Morton says, "the consumption does not seem to have its original so much from the breaking or gaping of a small vessel as from the inordinate and hectical state of the blood."

When consumption follows hæmoptysis the lungs become stuffed with hard glandules or tubercles. "Chalky stones bred in the lung when they are sharp and angular," and other pointed foreign bodies such as nails or pins, may tear the lung and cause hæmoptysis, and thence ulcers in the lungs.

Morton distinguishes a special scrofulous variety of consumption in which—

> "the blood by reason of its preternatural acrimony being, as it were coagulated, and so unable perfectly to unite the new chyle to itself and, the solid parts, is wont to throw it in a larger quantity than is convenient upon the glandulous parts ..... and what happens in other glandulous parts happens also in the lungs themselves, which are everywhere full of innumerable glandules, but of some more conspicuous ones, upon the windpipe and the branches of it, though in their natural state they are not so easily discerned: so that 'tis no wonder if those that have the king's-evil, who are frequently subject to glandulous swellings in other parts, are likewise many times affected with such kind of tubercles even in the lungs themselves."

But, whether conscious or unconscious of a certain ambiguity in his description of this variety of the disease, he adds that the most certain diagnostic sign of this form "is to be taken from glandulous swellings in the external habit of the body accompanying of it, or at least preceding it." Morton says that this variety of phthisis was the commonest in his experience and furnished most cases of recovery.

Value of Morton's Work.

In estimating the value of Morton's work we must consider his relation to Sylvius, although he makes no reference to the writings of the latter. The Opera Medica of Sylvius were published ten years before the appearance of Morton's Phthisiologia, and it is unlikely that Morton was unacquainted with the older work, as the reputation and authority of Sylvius were then so great. Morton adopts Sylvius's view of the glandular origin of tubercles in the most thorough-going fashion, and follows him in other points. Sylvius, as we have seen, was far in advance of all previous authors in asserting that tubercles were often found in the lungs of consumptive persons, and in attributing the formation of vomicæ to the softening and suppuration of tubercles.

Morton went still further and maintained that tubercles were found in the lungs in all cases of consumption, whatever its origin might be. But in the seventeenth century the word tubercle was used in the etymological sense, and as yet possessed no specific pathological significance.

Both Sylvius and Morton insisted upon the contagious nature of this disease, a view which had long prevailed and seems to have been held by Galen and Aristotle.

(To be concluded.)

A GENERAL meeting of the Institute of Hygiene has decided to elect women to the governing body of the Institute.

THE STANDARDISATION OF THE WASSERMANN REACTION.

BY W. D'ESTE EMERY, M.D., B.SC. LOND.,
CAPTAIN, R.A.M.C. (T.); DIRECTOR OF THE LABORATORIES, KING'S COLLEGE HOSPITAL.

WE may look at the Wassermann reaction from two standpoints—as a means for the diagnosis of syphilis and as a highly complex reaction involving the recognition of the presence, and if possible an estimation of the amount, of a hypothetical substance which occurs in the blood in syphilis and few other diseases. For the former purpose I see no reason to change my opinion that a method involving the use of crude serum is the best, and that its rapidity and freedom from certain possibilities of accidental error more than outweigh its disadvantages. This, however, is by the way. The so-called "original" method is now required officially, and I have now used for more than two years one of the recognised modifications of the test.

The Nature of the Problem.

I propose to discuss the theoretical basis which must underlie any attempt to bring about a standardisation of the process, so that an accurate measure may be made of the strength of the reaction in any given case, and so that the workers in different laboratories may get concordant results. There is a third problem intimately bound up with these two: What strength of reaction are we to regard as being necessary to diagnose syphilis? This cannot be solved until we have a standard by which we can compare our results.

In a Wassermann reaction which is just positive we may consider that the three reacting substances—syphilitic serum, complement, and antigen—are in a state of equilibrium. If we add a little more complement this remains free, but it can be absorbed by adding more serum or more antigen; if we add a little less antigen we can still get our positive reaction by using less complement, and so on indefinitely. We have to titrate our unknown substance, the strength of which we wish to determine, by means of two standard solutions, complement and antigen, the excess of either of which can be compensated for (within certain limits) by the corresponding excess of the other. Add to this the fact that in neither case can we standardise our reagents by ordinary chemical or physical processes, or obtain them in a state of purity, and it will be seen that the problem is one of extreme difficulty.

It is really even more difficult than this; for we test this absolute absorption of the complement by a test-reagent which is itself of extreme complexity, the mixture of red corpuscles and hæmolytic amboceptor. No two samples of red corpuscles are exactly alike; and even when we work with carefully preserved specimens of the same sample of blood we have no reason to know that this remains constant from day to day. Again, it is not easy to obtain exactly accurate emulsions of corpuscles, and I do not find that the point is gone into much in actual practice. The hæmolytic amboceptor, again, is a source of difficulty, in that it can only be standardised by the use of complement, which in turn can only be standardised by the use of amboceptor. We seem to have no starting-point. And the strength of the test-fluid is not a matter of indifference. A reaction which appears positive when corpuscles sensitised with a small amount of hæmolytic amboceptor is used may appear negative when the latter ingredient of the test fluid is increased.

The Significance of the Reaction.

The question may be asked, How, in face of these facts, is it possible to get even reasonably trustworthy results in actual practice? And how is it that the results in one laboratory agree very fairly with those from another? The answer is that the Wassermann reaction varies enormously in strength, and that most reactions are so strong that they can be estimated by any technique. Thus, if we call the strength of the smallest reaction which we regard as positive 1, we often find reactions of 22, or somewhat more; and most of the cases that come to us to be diagnosed have a reaction of 4 or more, a strength which can hardly be missed. It is in the weak reactions that we get discrepancies, and it is the object of this paper to show a method, and, I believe, the only method, by which these discrepancies may be avoided.

It must be borne in mind that this is not altogether, and perhaps not mainly, a matter of technique or of ingredients; it is largely a matter of the personal equation of the experimenter. He has to deal with sera which, under the conditions of his test, will absorb all amounts of complement, from the smallest to the greatest. Some of these amounts, he knows, do not indicate syphilis; others equally certainly do—Where is he to draw the line? Thus, under the conditions in which I work I may get an absorption of complement which varies between 1 and 3000. (I am taking arbitrary figures.) An absorption of 5, or 10, or 20 I know does not indicate syphilis; it is a clear negative reaction. I am equally certain that an absorption of 100 does indicate syphilis; it is a clearly definite, though not very strong, positive reaction. What am I to say to an absorption of 75 or 80? Of course, the history of the case may give me some clue. If the serum is from a patient with a doubtful sore, or from a patient who has just finished a course of treatment, the diagnosis is obvious: I have to deal with a weak positive reaction. But where the history is not forthcoming I cannot possibly say what the significance of the result may be, nor can anyone help me.

There is no authoritative guide, nor can there be one until a large mass of experience has been accumulated, taking absolute units and not the arbitrary figures I have used above for sake of example. Under these circumstances every serologist is a law to himself. If he is naturally of a cautious disposition he pitches his standard low, so that he can never by any chance diagnose a case as syphilis if it is not so; by so doing he will sacrifice some accuracy, but he will never make the mistake (which is often so serious) of accusing a person of having syphilis when he has not. He will, however, miss a few early cases, and he will occasionally say that a patient is cured when he is not. The pathologist who is more daring will get more accurate results in these early or late cases, but he will run the risk of occasionally diagnosing syphilis when it is not present. These cases where the reaction is weak or doubtful make up but a small proportion of the total number examined, and the results of the two workers will coincide in the great majority of cases.

The first essential is for us to agree on some unit, some standard, to which all results can be compared. It does not follow that the unit shall be one that is used in actual practice, or that the methods which are used in obtaining this standard shall be used by all workers; indeed, I think it would be a great pity if any uniform technique were imposed and made compulsory. But what is essential is that he shall be able to compare his results with a standard—to say, for instance, that his four pluses corresponds to McIntosh and Fildes's 4 4 0 0 0 0, and so on. When this has been done we shall be able to take the further step and to investigate on a large scale where the line is to be drawn between the positive and the negative, for we shall have a solid basis of comparison. As a matter of fact, it would be a great advantage if we could have as our unit the exact minimum strength necessary for the diagnosis of syphilis, so that we could report a positive reaction of 1 or 2 or 20 units, and we should in doing so convey to the clinician a very clear and definite understanding as to the strength of the reaction. Moreover, if this were done he would be able to send serum to one laboratory at one time and to another subsequently, and get results which he could compare directly the one with the other. This is an ideal, but it is one that can be obtained without much difficulty.

Description of Technique.

I shall now describe the technique which I use in general work, and which I have followed in the investigations which I am about to describe. In general terms I follow McIntosh and Fildes's technique very closely, the alterations I use being mainly dictated by convenience.

1. *Preparation of the Hæmolytic System.*

Here I use a 5 per cent. emulsion of sheep's corpuscles, the amount being measured by sucking up the required quantity in a graduated pipette. I do not centrifugalise to constant volume in a graduated tube, since I find that the mass of corpuscles thus obtained is sometimes very difficult to stir into a uniform emulsion, and may show a considerable amount of hæmolysis when emulsified. Moreover, the matter is not really an important one so long as the deviation from the 5 per cent. aimed at is not great; the whole process, including the standardisation of the complement, is carried

out with the same emulsion, and any trifling error is unimportant. It is highly advisable to prepare all the sensitised emulsion that will be required for the day at once, otherwise a small error may creep in.

The question of the dose of amboceptor.—Here we have our first difficulty. We can only standardise our amboceptor by means of complement, and we cannot standardise our complement until the strength of the amboceptor is known. The term "unit of amboceptor" by itself is meaningless, for by altering our unit of complement we can, within certain limits, alter our unit of amboceptor. The usual method is to estimate the strength of the complement in presence of an excess of complement: thus, McIntosh and Fildes estimate their amboceptor in presence of a 50 per cent. dilution of guinea-pig's serum, and repeat the test so as to avoid getting abnormal results from the use of a weak serum.

I standardise my amboceptor in presence of the same amount of complement as is used in the test (2½ units per c.cm.) in the following manner: knowing from previous experience, or from testing out with a previously studied batch of amboceptor serum, the approximate amount of serum required to sensitise 20 c.cm. of 5 per cent. emulsion of corpuscles, I estimate the strength of my complement in the way McIntosh and Fildes describe—i.e., by taking a 1 in 25 dilution of the serum, measuring out 2/20, 3/20, 4/20, &c., of a c.cm. and making up to 1 c.cm. with saline. To these tubes are added ½ c.cm. of the sensitised emulsion and the mixtures are incubated for half an hour. If necessary a second estimation is made, using double amount of a 1 in 50 dilution. This gives a unit of complement in relation to the emulsion of corpuscles used in estimating it.

The new amboceptor is now in its turn estimated, using the same strength of complement as is used in the test proper—that is, 2½ units—as already determined. To do this a solution is prepared containing 5 units of complement in 1 c.cm., and a series of tubes put up each containing ½ c.cm. To these are added various dilutions of the amboceptor to be tested, and then ½ c.cm. of 5 per cent. emulsion of corpuscles, and the mixture incubated as before.

	c.cm.	c.cm.	c.cm.	c.cm.	c.cm.	c.cm.	c.cm.	c.cm.
Complement*	0·5	0·5	0·5	0·5	0·5	0·5	0·5	0·5
Amboceptor†	1/100	1/1000	1/10,000	1/1200	1/1400	1/1600	1/1800	1/2000
Hæmolysis	Complete		Trace	Complete				Practically complete

* 2·5 units. † 0·5 c.cm.

Thus, each ½ c.cm. of amboceptor contains about 2000 hæmolytic units, or each c.cm. contains 4000 units—the units being estimated for 2½ units of complement per c.cm.

In actual practice I use 40 of these amboceptor units per c.cm. Where such a large excess is used small variations in the amount taken do not affect the result.

Where still greater accuracy is required the complement may be again standardised by means of the new unit of amboceptor thus obtained, and the latter re-standardised by means of the new unit of complement, and thus by a series of approximations very accurate figures may be obtained. It is necessary to emphasise the fact, however, that these are not fixed units, they are only relative the one to the other, and if it were necessary to make a complete fresh start there would be no means of getting the same standard as before. The saving point is the fact that the amboceptor serum varies but slowly, and owing to this fact the units used in any given laboratory maintaining a standard technique vary but slightly from time to time.

Having calculated the amount of amboceptor serum required, the necessary amount of corpuscles are placed in a graduate containing a little less than the required amount of saline, the serum is added and well stirred in, and the volume made up to the required total. Thus, to make 40 c.cm. take about 35 c.cm. of saline, add 2 c.cm. of corpuscles, 4/10 c.cm. of amboceptor (having the strength given above), and stir well; then make up to 40 c.cm. exactly. I prefer to begin work by preparing this mixture and letting it stand a little time before use, so that the corpuscles may get completely and uniformly sensitised. In hot weather it is a good plan to let it stand in cold water.

2. *Standardisation of the Complement.*

Prepare a 1 in 25 solution of the guinea-pig's serum, and place 2/20–3/20, 4/20, &c., of this dilution in a series of tubes as before, make up to 1 c.cm. in all cases, and add ½ c.cm. of the sensitised emulsion. Incubate, and read off in half an hour, holding the tubes against a dark background and looking at them by transmitted light. This is the most difficult part of the process if really accurate results are required, though it is not easy to go so far wrong as to give results which shall have any incorrect clinical significance. Greater accuracy may be obtained by using a dilution of 1 in 50, and a useful device is to allow the tubes to settle for an hour or so, so as to be able to compare the upper part of the tube, which will now in any case be clear owing to the subsidence of the undissolved corpuscles, with the lower part, and thus to see whether there is or is not a trace of undissolved corpuscles. Another method is to centrifugalise and see whether there is a sediment, but this does not give exactly the same results as the former. Whichever method is used it must be kept to throughout.

3. *Preparation of the Antigen-complement Mixture.*

Here I deviate a little from McIntosh and Fildes's method, in that I make up my mixture so that the necessary 2½ units of complement and the requisite amount of antigen are dissolved in 0·9 c.cm. and not in 1 c.cm., as in their method. I do this simply because I use 0·1 c.cm. of serum for the test, and I get, in all cases, the volume of the fluid to be tested, whatever it may be, to 1 c.cm. exactly, this being the amount used in the standardisation. The calculation is made just as if I were going to make up the amounts in 1 c.cm., but they are actually dissolved in 9/10 of the amount. Thus, to make nominally 50 c.cm. of mixed antigen-complement, supposing the amount of antigen required to be 4 per cent. and the complement to have a minimal hæmolytic dose of 5/20 c.cm. of a 1 in 25 solution, I proceed as follows. The amount of guinea-pig serum required is—

$$5/20 \times 1/25 \times 2\tfrac{1}{2} \times 50 \text{ or } 1{\cdot}25 \text{ c.cm.}$$

(The amount necessary for 50 c.cm. can always be found by dividing the figure representing the number of twentieths of a c.cm. of the solution necessary for complete hæmolysis by 4.) Into a graduated measure I put about 40 c.cm. of saline, then add the antigen (2 c.cm.), and then 1·25 c.cm. guinea-pig serum, mix well, and make up to 45 c.cm. exactly. This gives me in each 0·9 c.cm. the amount McIntosh and Fildes put in 1 c.cm.

Two questions now arise for discussion.

(1) Is there any advantage in standardising the complement in presence of the antigen? I think there is only this advantage: that you are enabled to state at once, and without calculation, what is the actual amount of complement you are using in the test. Thus I find by repeated observations that the fluid prepared as above with the antigen I use, and calculated to contain 2½ units of complement per 0·9 c.cm., actually contains 2 units, and this is the amount used, therefore, in the test. This is shown as follows:—

A complement-antigen mixture containing 2½ (calculated) units of complement is tested for complement in the usual way: 7/20, 8/20, 9/20, &c., of the mixture are placed in tubes, made up to 1 c.cm. with saline, and ½ c.cm. of sensitised emulsion added. If there were no absorption of complement there would be complete hæmolysis in the 8/20 tube, whereas, as a matter of fact, it is not complete until tube 9/20, so that there are two free units of complement in each 0·9 c.cm.

I have thought it necessary to describe the method used for determining the anticomplementary power of the antigen (or what comes to the same thing if the complement is also estimated in saline), since some of the methods put forward are not, in my opinion, of any value. For any method to be useful the conditions must be exactly the same as in the test proper.

(2) Is there any advantage in mixing the complement and antigen (both prepared of double strength) just before the test, and not making up a large volume of the test-fluid for use throughout the series of test? I do not find that there is any continued absorption of complement for the first two hours at least after the two fluids are mixed. There is a very rapid absorption of the amount I have stated, but after that the composition of the fluid remains constant for a considerable time. Where I have wished to carry out a prolonged series of tests with the same mixture I have kept it in a jar of ice-water, but as a rule and for ordinary purposes no appreciable error will come in if it is kept for an hour or two at room temperature.

I may point out that in the actual practice of the Wassermann reaction there is no great object in making these

estimations in too refined a way or of attempting too great accuracy, since the amount of anticomplement varies in different sera, and unless this is estimated in each case the observer does not know how much complement remains for specific absorption, however carefully he may have standardised them in the first instance. For research work or for the preparation of standards it is another matter, and every precaution should be taken at every stage of the process.

4. *The Actual Test.*

I work with only half the amount, but for the sake of simplicity will describe the method as if the full 1 c.cm. was used. The preparation of the sera follows on usual lines and needs no comment. They are placed, each tube carefully numbered, in a tray of plasticine with a blank space at the left hand end. Into the row just in front of the row of a Wassermann rack in which the holes are numbered 1, 2, 3, &c., is placed a series of tubes into each of which 0·9 c.cm. of antigen-complement mixture is pipetted. The first serum tube is taken out of the plasticine and 0·1 c.cm. withdrawn by means of a fine-pointed capillary pipette. This is washed out into the mixture in the tube, which is then placed in the hole just behind it, numbered 1, and the serum tube is placed in the blank space at the left, so as to leave an empty space between it and tube 2. The pipette is then washed out with saline and the process repeated, so that each serum tube is gradually shifted one place to the left, and each complement-antigen tube is moved one row back. By this method I think I reduce to a minimum the possibility of mixing the tubes; and this, I am convinced, is one of the chief errors of the Wassermann reaction, and will continue so long as human nature remains fallible and large batches are in vogue.

When the rack is filled in it is placed at once in the water-bath and incubated for 20 minutes. Then ½ c.cm. of sensitised corpuscle emulsion is added to each tube brusquely, and the rack returned to the incubator.

No controls are put up in the first instance, since it is unnecessary in the case of a negative serum; the only purpose that can be achieved by a control is the detection of anticomplementary substances in the serum, and if full hæmolysis takes place these are not present in excessive amounts. Where there is a positive result, and especially a partial positive, controls are necessary. For these I use 1¼ or 1½ units of complement per c.cm. in saline, again making up the solution in 9/10 of the calculated amount. These amounts leave, as I shall show, approximately one free unit of complement when 0·9 c.cm. is mixed with 0·1 c.cm. of most sera, and should therefore give complete, or almost complete, hæmolysis.

5. *The Quantitative Test.*

This is carried out as follows. Taking a series of 6 tubes, I place 0·9 c.cm. of complement-antigen mixture in the first and 0·5 in each of the remainder. To the first tube I add 0·1 c.cm. of the serum to be tested; this is pipetted carefully to the bottom of the fluid, so that it does not mix therewith at present, and the pipette washed out in the supernatant fluid. Then, with a pipette showing 0·5 c.cm. I mix the two fluids quickly and remove 0·5 c.cm., which is immediately carried over into the second tube and mixed in. This operation is repeated until I come to the last tube, when the last ½ c.cm. is rejected. The whole process is very quickly carried out, and gives a series of six tubes containing 0·5 c.cm. of fluid each, the first containing 1/20 c.cm. of serum, the second 1/40, and so on to the last, which contains 1/640 c.cm. (These figures would have to be doubled to be comparable with the qualitative test, which was given as if carried out in 1 c.cm. of total bulk.) It is rarely necessary to go beyond the sixth tube, but exceptionally a specimen may be found which is even stronger than this and gives partial deviation when 1/640 c.cm. of serum is present in 1 c.cm. of complement-antigen mixture.

The results are stated as in McIntosh and Fildes's method, calling complete inhibition (no hæmolysis), 4; nearly complete inhibition (a trace of hæmolysis), 3; hæmolysis of approximately half the corpuscles, 2; nearly complete hæmolysis, 1. Thus, a result stated as 444200 would indicate that 1/40 c.cm. of serum made up to 1 c.cm. with complement-antigen mixture would give complete inhibition, whilst a mixture of 1/80 c.cm. of serum made up to 1 c.cm. would leave enough complement free to hæmolyse about half the corpuscles.

We can, with no great degree of error, state our results in terms of the number of units of complement absorbed: thus, the result given above might be taken as indicating that 1/40 c.cm. of serum absorbed 2 units, or that 1 c.cm. would absorb 80 units. We may also read them off approximately in terms of "standard units": thus 400000 is equal to one unit, 440000 to 2, 444000 to 4, and so on. There are, however, some corrections which have to be made before regarding this as a scientifically accurate, though it is a fairly close, approximation. I will leave the question of these corrections for subsequent discussion; it is sufficient for my present purposes to explain the methods by which I have obtained the results I now have to quote.

Standardisation of Antigen.

Let us now revert to the main object of the inquiry, and see what fixed point we can find to act as a starting-point for the standardisation of our methods. The first and most obvious suggestion is the antigen. Would it not be practicable to have a standard antigen, issued by authority, which all workers might use, and thus obtain concordant results? Antigen is fairly constant (to say the least), and presents at any rate some approximation to a definite chemical substance.

The first question that arises is this: If we prepare antigens from similar materials by identical processes, will they be *equal, or approximately equal, in action?* I have carried out a good many experiments on these lines, and find that this is the case.[1]

For example, three antigens were prepared with 10 per cent. of sheep's heart in absolute alcohol (10 g. of heart-muscle with 90 c.cm. of absolute alcohol) and compared for their antigenic property. Mixtures were made of these three antigens with the same sample of 1 per cent. alcoholic cholesterin, and 4 per cent. dilutions were made with the necessary amount of complement, the same, of course, in all cases. Quantitative tests were then made with the same batch of syphilitic serum, and the results were found to be exactly the same; thus, in one experiment the serum (a very strong one) gave 44444430 with each sample of antigen, and when the seventh tube in each series (carefully selected so as to be of uniform width) was centrifugalised and the supernatant fluid compared with its fellows, no appreciable difference could be detected.[2]

These experiments have been frequently repeated, and as far as sheep's heart is concerned I have no doubt that an almost absolutely constant antigen can be prepared in this way. (I should say that I have always worked with fresh heart—not frozen—but that I have taken no especial care to see that it is equally fresh on all occasions.) There is one proviso: the solution of the active ingredient or ingredients is somewhat slow, and I find it takes at least a week for the antigen to get to its full strength, and it is better to leave it 10 days before use. I have made careful comparisons between two batches of antigen prepared from the same sheep's heart, the one part simply cut up into small pieces, the other minced fine and ground up with quartz sand, and then shaken for some hours; the latter attains its full strength more quickly, but the ultimate result is the same in the two.

In actual practice I use three extracts prepared from three hearts. They are kept separate, and I take 1 c.cm. of each, to which is added 2 c.cm. of cholesterin.

Secondly, as to the *keeping power* of the antigen. Strictly speaking, we cannot determine this, for we can only determine the antigenic power of an antigen by reference to a syphilitic serum, and we have as yet no assurance that this will remain sufficiently constant for our purpose. We can overcome the difficulty in this way: if we prepare several antigens at different times—say a month apart—and compare them from time to time, using them as antigens with syphilitic serum—any serum—then, if they remain constant, the results ought to be the same in all cases. This is what actually happens:—

Thus, antigen B was prepared on August 24th, 1917, and was therefore 1 month old at the time of the first test.

[1] This has already been stated by McIntosh and Fildes (Brain, vol. xxxvi., Part II.)

[2] The method by which the antigenic power of any antigen can be estimated in absolute units is deferred for subsequent publication.

Antigen C was prepared on Sept. 20th, 1917, and so was 4 days old. They were compared with serums X and Y on Sept. 24th, 1917. X gave 444442 with antigen B and 444442 with antigen C, but on a careful examination there was a minute trace of hæmolysis more in the last tube with antigen C; the amount was only just perceptible, and may have been due to the fact that full solution had not yet occurred. Y gave 444441 with antigen B and 444441 with antigen C. Here, again, the same minute difference could be detected on careful examination.

The test was repeated on Sept. 25th, with the same sera. X gave 444442 and 444442 with the two antigens, no difference being perceptible in the last tubes, and Y gave 444442 in both cases, there being a minute difference in the last tubes.

It was repeated again on Oct. 1st. Serum X gave 444442 with both antigens, but there was a minute difference in the last tubes; the same with Y.

The result of these preliminary experiments was to show that the antigenic power of the two antigens was practically identical, C being if anything a shade weaker than B, but the difference was extremely minute: it was hardly too large to be the result of experimental error, but it ran fairly constantly throughout the early part of the series, which was as a matter of fact larger than those I have published. Tests throughout November and December showed that both antigens had attained exactly the same strength.

They were tested again with other sera at intervals, and another antigen, D, was added to the series on Dec. 1st, 1917. This was found after a fortnight to have exactly the same strength as the other antigens, and on a standardisation on Jan. 15th all three antigens gave exactly the same readings with every serum with which they were tested, three in number. Thus, the last test (July 29th, 1918) was carried out with a comparatively weak serum, which gave 430000 with each antigen, and when the tubes showing partial hæmolysis were centrifugalised and compared, not the minutest difference could be seen between them.

Thus we find that three antigens prepared by identical methods from similar materials gave identical results when tested for their antigenic power within a fortnight after being made, and at intervals of 10 months in the case of two of them and 7 months for the other. I may say that the anticomplementary power (which is much less important) was also tested, and was found to be constant.

Now, of course, it is possible that all these antigens were altering exactly uniformly, and that when each began it happened by chance to be of just the same strength as had been reached by the preceding in their process of deterioration, but this was unthinkable. The only probable explanation, which I have no doubt is the correct one, is that antigen is a stable substance, and shows no falling off in strength in ten months at least.

There is one point on which I must lay emphasis, since in this my practice differs from that in use by most serologists. I always keep my antigen on the magma of heart from which it has been extracted. I have had sudden changes on many occasions in antigens which had been pipetted or filtered from the deposit, but, as I have said before, never in one that has been kept in contact therewith. I suggest that the substance or substances which act as antigens are sparingly soluble in alcohol, so that they form a saturated solution under the conditions of the experiment. If the stopper is kept out of the bottle, some of this active substance is thrown down; or if a little alcohol gains access when the pipette, wet with alcohol, is inserted, a little more is taken up. (Of course, no one would pipette up his antigen with a pipette wet with water.)

This fact appears to constitute an excellent starting-point for the standardisation of the Wassermann reaction; and so, within limits, it is. It will enable us to fix a constant unit for the reaction, one which can be reproduced at any time by anyone if the official standard is lost. I should suggest as a tentative unit *the strength of serum which will just give complete absorption of two units of complement when 1/10 c.cm. of the serum is incubated with 9/10 c.cm. of 4 per cent. antigen, prepared in the way I have described.* This is an excellent clinical standard. I have had experience of its use in some thousands of cases, and with one or two exceptions (in none of which could the presence of syphilis be excluded absolutely) I have never found a positive reaction, using this standard, in a non-syphilitic case. Whether it can be made a little delicate (say by lowering the amount of complement to 1·75 or 1·5) remains for future investigation.

But further consideration will show that the use of a standard antigen, though of great value, does not help us very much when we have to deal with serologists all over the country making Wassermann tests by very different methods. For if a worker uses the antigen in different strengths or in different proportions he will have to test out this standard antigen for himself, and he might just as well make it in the first instance. Again, it does not meet the indication of providing a fixed unit to which all results, by whatever method they are obtained, can be compared. For instance, a standard antigen such as I have described would be quite useless to anyone following Browning's technique, and any results obtained by him would still remain a sealed book to anyone who was used to other processes.

Standardisation of Serum.

We turn, therefore, to the third ingredient of the first stage of the reaction—the serum. If it were possible to prepare a standard serum of constant strength the problem would be solved. This would be of use in two ways.

In the first place, by using it as a control, worked out quantitatively in every batch of tests, it would be obvious if at any time the conditions altered and the results were not in series with those that had gone before. For example, if the standard serum gave a reaction of 444000 on previous occasions, and then gave only 440000, it would be obvious that something was wrong—probably either the complement had been estimated too high or the antigen had lost potency. The experimenter might then either recalculate his results on this basis or, preferably, scrap them and test them out again. I now use a standard control serum constantly for this purpose.

In the second place, the serum could be used for any method of testing and the results stated in absolute units. For example, suppose we take the unit I have suggested provisionally, and we have to deal with a serum giving 444000. This will be of about 4 units strength, since each 4 represents a serum of half the strength of its left-hand neighbour. When the serum is tested quantitatively by another method it might give a result which the experimenter might choose to express by saying that under the conditions of his experiment it had absorbed 12 units of complement. In this case each of his units would be equivalent to 3 standard units, and might be so expressed, so that his report would read "positive, absorbing 12 units of complement, equal to 4 standard units." I need hardly say that it would not follow that all his results need be worked out fully quantitatively. As a check on his method and to see whether his positives and negatives came out correctly it would only be necessary to do one full quantitative test—that one the control serum.

I believe this is quite practicable, indeed quite easy of accomplishment.

Constancy of the Serum.

The first question that presents itself is this: Does the serum remain constant for a length of time sufficiently long to allow it to be used in this way in practice? I shall show that it does.

The sera used in these observations were collected from syphilitics as a part of the intravenous injection of salvarsan products, and the greatest care was used in securing absolute asepsis. The specimens were collected in test-tubes (the angled tubes described in THE LANCET[3] were found to be of the greatest value in securing a full crop of serum), and after complete separation had occurred the serum was pipetted into a second tube until complete subsidence of the corpuscles had taken place or it was centrifugalised. It was then pipetted into sterile glass ampoules, white for choice, and the tips sealed, care being taken that no serum remained in the tip to become charred during the sealing. It was then heated to 58° C. for 15 minutes.

The first series of experiments dealt with samples of the same batch of sera kept: (1) at the room temperature, (2) in the ice-chest, and (3) frozen solid in ice and salt. Two sera, both from untreated secondary cases, were used, and each was tested with two antigens. One serum (176) gave 444420 with each antigen and the other (180) gave 444442. (There was a minute difference between the results with the same serum and the two antigens, due to the latter not being of exactly the same strength; this was very small, and apart from it all the readings were identical within the limits of experimental error.) This was on Sept. 21st, 1917, the sera having been collected on Sept. 18th and Sept. 20th respec-

[3] THE LANCET, 1917, i., 597.

tively. They were re-tested with the same results on Sept. 25th, Oct. 1st, and Oct. 16th. The experiment had then to be discontinued, owing to the stock of serum running low.

This experiment showed clearly enough that the change, if it took place at all, was very slow, and, further, that there is no advantage in keeping the serum in the ice-chest, or frozen, at any rate for a period up to three or four weeks. This is a great practical advantage. Of course, it may be suggested that the serum got weaker, but that the antigen altered simultaneously and *pari passu* with it. To assume this we should have to believe that eight substances (the two antigens and the six specimens of serum) all altered at exactly the same rate; this is extremely improbable, and the only tenable explanation is that all the specimens, antigen and serum, remained constant throughout the experiment.

This has since been abundantly confirmed, and I have now ample evidence that syphilitic serum, collected aseptically and free from corpuscles, will keep for at least a month without appreciable alteration. If kept indefinitely it does fall off gradually, and I am now investigating, as occasion arises, the speed at which it does so. Such experiments are naturally slow, and I have at present no figures to quote, but I may give the following figures of five sera which have been kept for considerable periods of time.

	207	208	209	212	233
Dec. 12	444420	443000	442000	430000	—
Dec. 19	444420	442000	441000	420000	—
Jan. 4	444430	442000	442000	430000	—
Jan. 11	444430	442000	442000	430000	443000
Jan. 18	444430	442000	442000	430000	443000
Jan. 29	444420	443000	442000	420000	442000
Feb. 5	444430	443000	443000	100000	441000
Mar. 19	444430	443000	442000	100000	441000

These observations, I may say, were carried out without any extraordinary precautions as to accuracy, as a part of the routine Wassermann examinations, which may account for the occasional discrepancy in the last significant figures. Here it will be seen that serum 212 (which was a weak one to start with) fell off nearly to nothing during the experiment, whilst the others remained practically constant. I may point out that a falling off of from 444440 to 444400 represents a diminution eight times as great as one from 440000 to 400000. I should also like to point out that I have seen in one serum at least indications of a decided rise after it had been kept for a long time. The subject teems with questions for further investigation, but for the present I will content myself with stating that Wassermann sera do not alter appreciably in strength for a month. I believe I am well within the mark.

The Question of Anticomplement.

Serologists to whom I have quoted my figures have objected that they were obviously impossible, since the serum *must* get stronger from the development of anti-complement. I need hardly point out that the usual teaching is that serum begins to get anticomplementary within a few days after collection, and that this property of bringing about non-specific destruction of the complement vitiates any results obtained except with fresh serum; the anti-complementary power, it is stated, can be destroyed by a fresh heating to 55° or 60° C.

I find myself quite unable to agree to either of these propositions, and I do not remember to have seen any detailed figures on which they are based. My experience is (1) that sera collected aseptically and free from corpuscles are never anticomplementary to an extent sufficient to nullify the Wassermann reaction when carried out as I have described above; and (2) sera kept aseptically either do not alter at all in their anticomplementary power, or, if they do so at all, only to an insignificant extent, and one hardly beyond the range of experimental error. To give the data on which these statements are based I must give my technique. There are two methods.

(1) Having tested out the complement in the usual way, prepare a dilution of such a strength that there is ½ unit in 0·9 c.cm.; it may be necessary also to use a solution containing 1 unit in 0·9 c.cm. if very strong anticomplementary sera are in question. To 0·9 of one of these solutions add 0·1 of the serum to be tested, mix and incubate for 20 minutes; then add ½ c.cm. of the emulsion of sensitised corpuscles and incubate until hæmolysis has gone on as far as it will. The process is slow, and about three-quarters of an hour is necessary. Prepare a series of tubes showing the effect of various fractions of a unit of complement thus: prepare first a solution containing 1 unit of complement per c.cm.; into a series of tubes put 1/20, 2/20, 3/20, &c., of this solution and make up to 1 c.cm.; add ½ c.cm. sensitised emulsion and incubate. When hæmolysis ceases centrifugalise the tubes; the clear solution will show the amount of hæmolysis given by 0·05, 0·1, 0·15, &c., of complement. Compare the hæmolysis in the tube to which serum has been added; the difference will show the amount that has been absorbed. Thus, if 0·1 c.cm. were added to 0·5 unit of complement and the resulting hæmolysis was equal to 0·2 unit, it follows that the serum absorbed 0·3 unit. The advantage of this method is that it requires only one tube for each serum to be examined, and when a series is to be tested it is very convenient. It is useless for sera showing hæmolysis.

(2) In the second method a series of solutions containing 1·125, 1·25, 1·375, 1·5, &c., units of complement per 0·9 c.cm. are prepared, and to each 0·1 c.cm. of serum is added. The mixture is incubated and the corpuscles are added in the usual way, and the point at which complete hæmolysis takes place is read off. This, less unity, gives the anti-complementary power of the serum. This method is rather wasteful in serum, but it gets rid of the troublesome process of preparing the standards, and it can be carried out with tinted serum.

Whichever method is applied the results are substantially similar, and the usual strength of a serum is about 0·25; that is to say, under the conditions of the Wassermann reaction about 0·25 of a unit is absorbed in the first tube by non-specific absorption by the serum. Very rarely the amount exceeds 0·5, but I have never found it as high as 0·75. Now, I may point out that in the Wassermann technique which I have described there are two free complementary units to start with, so that if a whole unit is absorbed non-specifically there will still be complete hæmolysis and a negative reaction if there is no specific absorbing substance present. I have never found it anything like that amount; I am speaking, of course, of reasonably clear sera. But it must also be borne in mind that in a strong serum the anticomplementary action is reduced by dilution until it is inappreciable. Thus if the anticomplement were 0·5 in the first tube it would be reduced to 0·00625 in the fourth tube.

As regards the alleged increase in the anticomplement on keeping, I can only say that I have examined sera of all ages up to seven months, and have never found it to occur. Sometimes I have thought there was a very slight rise, but, as a rule, it keeps reasonably steady within the limits of experimental error; certainly I have never seen anything that would throw out the test. I ought to say that my test sera are heated to 55° for half an hour, or to 58° for a quarter of an hour once for all when they are potted off, and are not heated subsequently. I prefer white bulbs, as any turbidity due to bacterial growth would be visible. The bulbs are kept in the dark, at room temperature.

Absorption of Complement.

A few words are necessary with regard to the assertion that complement varies in regard to the degree with which it is absorbed by antigen in the presence of syphilitic serum. I have never found this to occur, although I have been carrying out the technique I have described above twice a week at least for the last two and a half years, and must have had experience of at least 250 complementary sera; and I may point out that in the tables of the strengths of sera on different occasions given above it is obvious that it did not occur, or such constant results could not have been obtained. It is proverbially difficult to prove a negative, and if a hundred complementary sera were investigated and showed constant results with the same syphilitic serum and antigen it would be open to anyone to argue that the hundred and first would have shown something entirely different. But if this variability actually occurs two results follow: (1) it will be impossible ever to constitute an absolute Wassermann unit, and (2) the comparative method which I suggest by the use of standard sera will be additionally useful.

My complement serum is always used the same day, in fact as soon as it has separated. Rarely it is used on the second day as well, and I find it gives exactly the same results on the second day as on the first with the same serum and the same antigen, although the strength may have fallen off very decidedly.

Method of Testing Strength of a Standard Serum.

I will now give in brief outline the method of testing the strength of a standard serum so as to get absolute results. An actual example may be of interest.

Complement tested. Unit found to be 10/20 × 1/50, or 0·01 c.cm.

Antigen-complement mixture prepared by adding 1 c.cm. of antigen to about 20 c.cm. of saline, then adding 10/20 × 1/50 × 5/2 × 25, or 5/8 c.cm., of complement serum, and making up to 22½ c.cm.

This mixture had added to it 2½ units of complement per c.cm. To test the amount actually present 7/20, 8/20, 9/20, and 10/20 c.cm. were placed in tubes, made up to 1 c.cm. and ½ c.cm. sensitised emulsion added. The first two tubes showed slight haziness, the last two were clear, indicating that 9/20 c.cm. contained one unit, or 0·9 c.cm. two units, the amount required. (I may say that I am not certain that there is not a slight error here, tubes containing antigen not being easy to read off for complete hæmolysis; the error, if it occurs, is quite trivial.)

First approximation. The serum was tested by the technique already described, and found to give a reaction of 420000. Thus, 0·1 c.cm. of undiluted serum gave a complete reaction under the conditions of the experiment, whilst the same amount of a 1 in 2 dilution did not.

Second approximation. Dilutions of the serum of 1 in 1¼, 1 in 1½, and 1 in 1¾, were prepared. The first and second gave no hæmolysis, the last a trace of hæmolysis.

Third approximation. A dilution of 1 in 1⅝ was prepared. It gave no hæmolysis.

Lastly, the anticomplementary power of the serum was tested and found to be 0·125.

Thus the serum contains 1·625 units of reacting substance. If I were issuing this as a standard serum I should issue it as giving a complete reaction at 1 in 1¼, a partial one at 1 in 2, and no reaction at 1 in 3; and these figures, I believe, would hold whatever technique were used. Such sera should be issued periodically by authority. If any experimenters would like to have them, in order to be able to compare their units with my own, I shall be pleased to send them to them on a small scale as opportunities allow.

Conclusions.

In this paper, therefore, I have attempted to show:—

1. That it is possible to prepare a standard Wassermann unit by the use of antigen prepared in a definite manner. I suggest that until further experience is obtained the absorption of two clear units of complement, tested in the manner described, shall be regarded as a standard unit, this being found to give good clinical results.

2. That antigen prepared in the manner described remains remarkably constant, and that if several specimens are prepared from different batches of similar ingredients, they will give constant results.

3. That syphilitic sera, prepared aseptically and free from foreign materials, remain constant for at least a month, and probably for much longer, at room temperature.

4. That the use of such sera affords an easy means by which any experimenter can obtain comparable results from time to time.

5. That the use of such sera, accurately standardised, will enable workers by any technique to obtain results which are comparable.

6. I suggest that the Wassermann reaction should be reported in terms of Wassermann units, either those which I have described or some modification thereof, the figures given by each laboratory being the same whatever the technique, and such as will indicate the number of times the serum is stronger than the weakest serum which will just give definite proof that the patient has syphilis.

TUBERCULOSIS SOCIETY.—Sir Malcolm Morris will open the winter session with an introductory address on "Past and Future of the Fight against Tuberculosis" on Monday, Oct. 28th, at 8 P.M. The meeting will be held at the House of the Royal Society of Medicine, 1, Wimpole-street, London, W., and is open to all practitioners of medicine.

A MATINÉE of one-act plays will be given at the New Middlesex Theatre, Drury-lane, London, W.C., on Friday, Nov. 8th, at 2 P.M., in aid of the Vanguard Farm for Disabled Soldiers and Sailors at Sutton Valence, Kent. Tickets may be obtained from Miss H. M. Ironside, 50, Lincoln's Inn-fields, London, W.C. 2.

A NEW TECHNIQUE OF HEART MASSAGE,

WITH A CASE OF RESUSCITATION.

BY T. C. BOST, M.D. WASHINGTON, D.C.,
TEMPORARY CAPTAIN, R.A.M.C.

With Remarks by A. NEVE, F.R.C.S.E.,
TEMPORARY MAJOR, R.A.M.C.; SURGICAL DIVISIONAL OFFICER, WAR HOSPITAL, DARTFORD.

IN reviewing the literature of heart massage we find that this procedure has repeatedly been done, and in many instances with complete success; but in the career of any one surgeon, however long it may be, the opportunity will present itself but once or twice, if at all.

The first reported case was not until 1898 and the first reported complete success was as late as 1902 by Starling and Lane, so that even now from a clinical point of view heart massage may be considered of fairly recent origin and application. Green[1] in 1906 reviewed the literature and gave an abstract of 40 published cases. Many cases have since been reported, but from the leading medical journals[2] of many countries it would be difficult to collect more than ten successful cases in the last ten years.

Early Operation.

Judging by the reported cases complete success depends upon prompt operation, only 6 to 8 minutes after heart stoppage. Mollison's case[3] made a good recovery after an interval of 13 minutes, but showed profound mental symptoms for several days. In view of modern physiological science and surgical skill, all will agree that heart massage should be done in cases of suspended heart action following an anæsthetic, which have failed to respond to the ordinary methods of resuscitation, and as these methods are in many cases of doubtful value they should not be relied upon. Schiff as early as 1874 demonstrated, by chloroforming dogs until the heart ceased to beat, that artificial respiration and stimulation by electricity were of no avail in restoring cardiac action, but that massage, directly applied, restored it after an interval as long as 11½ minutes; furthermore, that the shorter the interval of time that elapses before applying massage the higher the percentage of success.

The Methods Employed.

There has been a gradual evolution of methods of heart massage.

1. *The thoracic method.*—In this a flap consisting of the thoracic wall over the cardiac area is cut and turned back, the base being either inwards or outwards. The costal cartilages are cut through, the pericardium exposed, and sometimes opened. The proceeding is forcible and must accentuate shock. Many intercostal vessels and nerves are involved. Pneumothorax has occurred in several of the published cases, and it is not surprising that the successes were almost nil, and that the method has been abandoned.

2. *The abdominal route, subdiaphragmatic.*—It is a familiar fact that some pressure upon the heart can be effected from the abdominal side of the diaphragm, so it was a natural thought to apply such pressure when the heart's action was arrested during the progress of a laparotomy operation. When promptly applied the conditions were favourable to resuscitation (Gray, 1902; Igelsrud, 1904; Cohen, 1903; Sencert, 1905; Depage, 1905; Smith and Daglish, 1905; Ramsay, 1906). This method has probably been used at an early stage in many unpublished cases, and the promptitude has won success. It is also possible that some of these cases might have recovered without massage. It has been demonstrated that in a child whose thorax is small and tissues elastic compression is possible though difficult; but in the adult it would rarely be effective, as only the cardiac apex can be reached, and it slips away upward. Hence the need for the trans-diaphragmatic method to reach the base of the heart where the auriculo-ventricular nerve ganglia are situated.

Heart massage is a complex performance. In its lightest rhythmical form it may undoubtedly stimulate the cardiac nerves, but a gentle squeeze of the organ does more: it empties the blood from the flaccid, perhaps distended auricles into the ventricles, the blood current acts as the physiological stimulus to these, and then the coronary arteries supply fresh blood to the cardiac muscles; thus a

healthy circle is re-established, and is reinforced by the artificial respiration, which should be carried on the whole time.

3. The *trans-diaphragmatic abdominal* route has been several times adopted, probably only unsuccessfully because too late. It need not be condemned on the statistics hitherto available. As above pointed out, the successful cases of subdiaphragmatic massage were those in which an abdominal operation was being performed at the time of the heart failure. It was the facility and the promptitude which secured the success. The diaphragm was only incised in the late stages of the worst cases, as, for example, Green's second case, in which an hour after apparent death from diphtheritic syncope he incised the pericardium through the diaphragm, and by massage started a few contractions. What more could have been expected? or Mauclaire's cases after tracheotomy and other measures carried out for 30 minutes?

The trans-diaphragmatic incision seems in these cases to have been approximately antero-posterior, splitting the muscle fibres and gaining direct access to the pericardium. There is some difficulty in executing this manœuvre on account of the left lobe of the liver and the stomach; there is also some risk of injuring the musculo-phrenic artery and having concealed hæmorrhage; and the suturing of the opening in the pericardium and diaphragm is as difficult as it is also necessary.

Hence the advantage of the horizontal incision behind the left costal margin which we here describe.

Description of the New Technique.

The abdominal incision is made four inches long in the median line, extending from above the umbilicus well up into the xipho-sternal notch. The left costal cartilages are well retracted, bringing the anterior diaphragmatic insertion well into view. There should be a pillow under the waist. A two-inch incision, beginning one inch to the left of the median line, carried outwards behind the costal margin, cuts the fibres of the diaphragm near their insertion. A blunt instrument pushed in opens the pleural cavity, and the opening is rapidly dilated with two or three fingers of the right hand, so that the whole hand can then be passed into the thoracic cavity anterior to the pericardium. The hand is passed upward, the thumb behind the sternum and the fingers embracing the entire organ in the pericardium. The thumb compresses the right auricle and ventricle, and the base of the heart is effectively massaged. No vessels are injured in this incision, as the superior epigastric artery is internal to the incision and passes into the rectus muscle, and the musculo-phrenic branch enters the diaphragm through the cellular tissue behind the eighth or ninth costal cartilages and passes backwards, deeper than the incision. The liver and stomach, even if prominent, offer no obstruction to this route, nor is the pericardium in risk of being opened. During the massage the parts can be pressed round the wrist of the operator so that air is not sucked in, and there is no tendency to collapse of the lung.

Closure.—The incision is easily closed and made air-tight. The costal margin is retracted and the cut diaphragm pressed up while a continuous catgut suture is inserted by means of a strong curved needle and holder. While this is being done the assistant can make rhythmic pressure during inspiration relaxed during expiration so that any contained air may be expelled and no more be allowed to enter. The abdominal wound is then closed in the usual way.

Abstract of a Case.

Pte. M. P., aged 37, was severely wounded on Oct. 26th, 1917, both knee-joints being involved. There were prolonged treatment and several operations. By March, 1918, both knees were healed, the left knee ankylosed, and he was allowed up. A week later some vague shifting abdominal pains began to appear, with tenderness and some rigidity, first on right flank then on left, and an irregular temperature. He also had a cough. Diarrhœa alternated with constipation. A week later he had retention of urine, and the orderly officer passed a catheter; there was some pyuria and diminished quantity of urine. No casts were found. He was thin and losing ground, with a blood pressure of 155 mm. and leucocyte count 12,000. In consultation it was decided to perform laparotomy to determine the presence of any abdominal abscess, and the condition of the kidneys, some metastatic sepsis being suspected.

Operation.—On March 30th, after a preliminary hypodermic of atropine 1/100 gr. and morphia 1/6th, chloroform was slowly and carefully administered by the open method by an experienced anæsthetist.

Time-table.—11.45: Began anæsthetic. 11.55: Almost under. Anæsthetist asked the surgeon to wait a minute as the patient was not yet fully relaxed. 11.58: Respiration ceased, pupils dilated, and colour changed to waxy. No pulse could be felt. Artificial respiration at once begun, with rhythmical traction of his tongue, and head of table lowered. 12.0: Strychnine and ether hypodermically. Auscultated, no heart sounds. 12.10: Artificial respiration pumps air well into chest, but nothing spontaneous. Eyes staring open, pupils dilated and insensitive. Captain Bost made a 4-inch epigastric incision, passed his gloved hand in, and pressed on the heart through the diaphragm. The heart felt quite flaccid and slipped upwards so that only the apex could be pressed, and there was no response. 12.15: Artificial respiration continued, and some rhythmical heart pressure first by Captain Bost, then by Major Neve. 12.20: The case appeared hopeless, but Captain Bost proposed to insert his hand into the thorax, and did so, incising the diaphragm as described above; he passed his hand up under the sternum, outside the pericardium to the base of the heart, which he could then completely grasp, and began slow pressure. 12.25: At first the organ was completely flaccid; after perhaps 12 seconds a sort of muscular twitch was felt, followed by a very feeble contraction, which in a few more seconds became strong and regular. 12.30: Pulse felt, colour returned, and massage stopped; injected pituitrin; artificial respiration continued. The diaphragm was sutured. A rapid exploration of the abdomen was made by Major A. Neve. There was some free clear fluid and no pus nor any inflammatory adhesions. The kidneys felt large. The wound was sutured and dressings applied. 12.45: Bandaging completed. Breathing slowly. Strong visible cardiac pulsation. 1.15: Back in ward. Blood pressure 145 mm. 1.30: Continuous proctoclysis was begun. He lay comatose.

March 31st: Still in same state, pupils medium size, sluggish. April 1st: Still same state; has had no convulsions. Has slight emphysema over left chest. Takes only 1 or 2 ounces of peptonised milk at the time, as he swallows badly. Pulse still strong and rapid. April 2nd: Emphysema had disappeared. He is more comatose. Died at 5.30 P.M., 77 hours after the operation.

Post mortem (April 3rd).—The laparotomy wound was well closed and quite clean; also the incision in the diaphragm, which was quite air-tight. There was no pneumothorax and the chest looked healthy except some septic metastatic foci at the base of both lungs. The pericardium and heart looked healthy. Both kidneys showed small calculi and pyelo-nephrosis. The left ureter was partly blocked by the pus and gravel at the bladder orifice.

REMARKS BY MAJOR NEVE.

The striking success of Captain Bost's procedure in this case as regards the resuscitation of the heart's action after 25 minutes' absolute cessation proves the value of efficient heart massage. Without that the man was already dead. It was clear to all the five surgeons who were present that we were dealing with a case of primary heart failure under chloroform narcosis, due to the toxæmia of the patient's disease.

We could carry on the respiration without his muscles, but not the circulation. Subdiaphragmatic massage was inefficient, because it did not stimulate the cardiac nerve ganglia at the base; but after incising the diaphragm and grasping the base of the heart, 10 or 12 gentle squeezes started regular contractions, and the strong apex beat became visible to all onlookers. We have discussed the technique elsewhere. The incision was one which Captain Bost had previously planned on a cadaver.

It is unfortunate that this method was not adopted a few minutes earlier, as the prolonged pause in the cerebral circulation was probably in part responsible for the onset of coma; but had the kidneys and lungs been healthy the patient might well have recovered.

Conclusions.

1. We consider that this case illustrates the unique value of heart massage, and that the human heart can be resuscitated after a variable length of time—in this instance after 25 minutes. Nothing else could have re-started the cardiac action in this case.

2. *Type of cases for massage.*—All cases of suspended heart action following an anæsthetic, regardless of theoretical etiological factors, after a certain interval. Cases of asphyxia should also fall within this group.

3. *Length of interval.*—This should probably vary with individual cases, but should rarely be done under five minutes (unless the abdomen be already open), and certainly after eight minutes, though a longer interval need not bar the operation. The simpler methods of resuscitation, such as artificial respiration, tongue traction, sharp percussion over the cardiac region, and inversion of the patient, should begin in the first minute, but not be uselessly persevered in to the neglect of more efficient measures.

4. Subdiaphragmatic massage may suffice, especially in children, and if very promptly undertaken. But if only the apex is reached and the heart remains unresponsive the diaphragm should be incised and the base of the heart be massaged without further delay.

5. That no surgeon, even if relatively unskilled, should be content to abandon a case without giving his patient the benefit of direct cardiac massage.

6. We claim that this new technique offers a simpler method of approach and is a decided improvement upon

all other ways of doing direct heart massage, as it involves less risk of hæmorrhage, trauma, and shock, and can subsequently be more quickly and satisfactorily closed.

We are indebted to Lieutenant-Colonel Bond for permission to publish this case.

A MODIFICATION OF
WEBSTER'S TEST FOR THE PRESENCE OF T.N.T. IN URINE.

BY FRANK TUTIN.

(*From the Department of Biochemistry and Pharmacology, Medical Research Committee.*)

IT has been shown by Webster[1] that T.N.T., when taken by the mouth, or otherwise absorbed into the system, is excreted in an altered form in the urine, where its presence may readily be detected. The urine to be examined is first extracted with ether, then acidified with a mineral acid and again extracted with ether. In the latter extract the presence of the azoxy-compound formed by metabolisation from T.N.T. is readily shown by the development of a violet tint on the addition of alcoholic potash.

Possible Source of Error.

There is one possibility of confusion which, though it has probably been recognised by a number of workers, has apparently not hitherto been mentioned in published literature. Various purgatives (rhubarb, senna, cascara, &c.) contain substances (anthraquinone derivatives) which, when excreted in the urine, give under the conditions of Webster's test a red or reddish-violet colour, which might be mistaken for that produced by T.N.T. It is well known in medical practice that the urine of patients taking purgatives of this group will directly give a red colour with alkali, and this is rather loosely attributed to "chrysophanic acid." Chrysophanic acid is only one, and not the most important, of the substances concerned, and it seemed desirable to investigate the whole group from the point of view of their excretion and colour-producing properties, and to devise some modification of the T.N.T. test which would eliminate the possibility of confusion.

The results of this short investigation form the subject of this note. When I had completed it and had found that a slight modification of Webster's test made possible a clear distinction between the colour reaction due to T.N.T. and that due to any of the anthraquinone derivatives occurring in purgatives, I heard from Mr. Webster that he had himself come across the same possibility of error, that he had adopted the same modification of his test as that which I here suggest, and that he had found, like myself, that its introduction in any case sharpened and improved the T.N.T. reaction, whether anthraquinone derivatives were present or not.

My experiments were made firstly with the pure anthraquinone derivatives which occur in the different purgatives of this class, and secondly with doses of rhubarb root, since this drug contains all the known substituted anthraquinones present in the group.

The pure principles in question are rhein, aloe-emodin, emodin,[2] and chrysophanol ("chrysophanic acid"). They are all closely related chemically, the relation being briefly as follows: chrysophanol is a methyldihydroxyanthraquinone, aloe-emodin is the corresponding hydroxymethyldihydroxyanthraquinone, rhein the carboxylic acid yielded by the oxidation of aloe-emodin, and emodin is chrysophanol containing one additional, strongly phenolic hydroxyl group. These substances were each administered by the mouth in 0·1 g. doses, and in each case the urine subsequently collected, when examined by Webster's method, gave a strong colour reaction which might easily have been mistaken for that produced by T.N.T. On further investigating these four samples of urine it was found that the rhein had been rapidly excreted unchanged, whilst the other three anthraquinone derivatives had each undergone more or less oxidation, the aloe-emodin being entirely, and the chrysophanol partially, converted into the corresponding carboxylic acid (rhein), whilst a portion of the emodin appeared to be oxidised to the corresponding trihydroxyanthraquinone carboxylic acid, a substance which has not hitherto been known. In all cases, however, it was found that an ethereal liquid could be obtained which yielded no colour with alcoholic potash if the extracts obtained from the acidified urine were washed with dilute aqueous sodium carbonate before being treated with the stronger alkali. It was, moreover, found that the azoxy-compound formed from T.N.T., which is the substance which yields the characteristic "Webster reaction," is not removed from ether by treatment with dilute aqueous sodium carbonate.

Description of Modified Test.

These results, therefore, indicate a method by which anthraquinone derivatives may be eliminated from the ethereal extract to be tested by Webster's method, and it is recommended that the test should be conducted in the following modified manner:—

The urine should first be extracted with two successive portions of ether. This treatment removes any T.N.T. which may be present from accidental contamination, and also chrysophanol. The urine is then acidified with hydrochloric or sulphuric acid and again extracted with ether. During these extractions the addition of alcohol is usually necessary to cause the separation of emulsions. The ethereal extract of the acidified urine must then be extracted twice with dilute aqueous sodium carbonate, washed with water, and then treated with alcoholic potash, when the characteristic violet colour will be produced if derivatives of T.N.T. were present in the urine. If anthraquinone derivatives were present the sodium carbonate extracts will have a reddish-violet colour.

The method as originally described by Webster, and the modified procedure given above were then applied to samples of urine from three people who had previously taken respectively (*a*) 0·01 g. T.N.T., (*b*) 0·01 g. T.N.T. + 1 g. rhubarb root, and (*c*) 1 g. rhubarb root. When following Webster's procedure all three samples gave a positive reaction, but after treatment with sodium carbonate (*a*) and (*b*) gave reactions due to T.N.T. only, whilst (*c*) gave no reaction. Moreover, the colour yielded by (*a*) after treatment with sodium carbonate was a much purer violet and appeared more intense than before this treatment. This was due to the fact that sodium carbonate removes from the ethereal extract small amounts of substances which give a yellow or brownish colour with alkali, and therefore mask, to some extent, the characteristic colour of the "Webster reaction." The employment of the modified test here proposed would therefore appear to be desirable on all occasions when examining urine for T.N.T., even when the possibility of the presence of anthraquinone derivative is known to be precluded.

In conclusion, the author wishes to express his indebtedness to the Wellcome Chemical Research Laboratories, who supplied the specimens of pure anthraquinone derivatives which have been mentioned.

[1] THE LANCET, 1916, ii., p. 1029.

[2] Emodin monomethyl ether, another constituent of rhubarb, was not separately investigated, since this substance always behaves exactly similarly to chrysophanol, unless it suffers demethylation, when, of course, it yields emodin.

THE death is announced of Miss Agnes E. Weston, G.B.E., the "Sailor's Friend," at the Royal Sailor's Rest, Devonport, at the age of 78.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL (UNIVERSITY OF LONDON).—The University Entrance Scholarship in Anatomy and Physiology (value £50) has been awarded to Miss A. M. Freeman.

THE NATION'S TRIBUTE TO NURSES.—A meeting in support of the Hon. Sir Arthur Stanley's appeal to the nation for £100,000 as a tribute fund for nurses was held in Belfast on Oct. 17th. It was addressed, among others, by Mr. Henry McLoughlin, of Dublin, organising secretary of the movement in Ireland. The money raised in Ireland is to be invested in four Dublin trustees, and the interest is to be used on behalf of Irish nurses. It was decided to appeal for funds in Belfast, and office-bearers were appointed.

A NOTE ON

"ACUTE YELLOW ATROPHY" (?)

IN A MUNITION WORKER WITH A PSEUDO T.N.T. URINE REACTION DUE TO RHUBARB.

BY ERNEST GLYNN, F.R.C.P. LOND.,

CAPTAIN, R.A.M.C. (T.); PROFESSOR OF PATHOLOGY, UNIVERSITY OF LIVERPOOL.

(*Report to the Medical Research Committee.*)

THE patient was a female munition worker, aged 20, unmarried, and was employed in a T.N.T. factory from January, 1917, to June, 1918. Up to September, 1917, she worked in a "filling" room; here shells were filled with blocks of T.N.T., amatol coated with wax, and exploder bags containing T.N.T. Her duty was to handle the filled shells—she wore neither cap nor gloves. During this period her health was reported good—confirmed by her mother's statement. On Sept. 10th, 1917, for administrative reasons, she was transferred to a "cleaning" room, where she remained till death. She cleaned new or exploded brass cartridge cases for shells, which were covered with a small quantity of grease, by means of a weak watery solution of "nitre cake"; this is "the residue resulting from the manufacture of nitric acid and is an acid sulphate of soda containing 30 per cent. of its weight of sulphuric acid." She only handled the outside of the cases.[1]

Her health remained good until June 5th, when she vomited; on June 7th, as the vomiting persisted and slight jaundice appeared, she did not go to work; on June 12th she was unconscious, and next day was admitted to the Royal Infirmary under the care of Dr. J. C. Matthews, comatose, moderately jaundiced, temperature 101° F. Two ounces of urine removed with a catheter contained bile pigment and leucin, but no albumin; the biochemical laboratory reported that it gave the reaction of T.N.T. by Webster's test. The patient's temperature soon rose to 107°; there is no record of it before admission. She died 18 hours after admission—i.e., seven and a half days after stopping work and nine months after leaving the "filling" room.

Post-mortem.—The post-mortem was made 14 hours after death. Peritoneum: 4 oz., clear, slightly blood-stained, straw-coloured fluid. Very extensive petechial hæmorrhages becoming confluent over mesentery of small intestine and posterior surface of parietal peritoneum; a few hæmorrhages on visceral and parietal pericardium and posterior surface of visceral pleura. Liver: 41 oz., capsule not wrinkled, surface yellow ochre mottled with small capsular hæmorrhages; on section very soft and uniformly yellow; no fibrosis or compensatory hypertrophy. Gall-bladder: normal (the liver became much greener after preservation in formalin). Spleen: 6 oz., firm, normal. Stomach: post-mortem autolysis, a few hæmorrhages. Ileum: lower end intensely congested, a few hæmorrhages. Suprarenals: normal. Pancreas: normal. Kidneys: 5½ oz., rather pale. Ovaries: small hæmorrhages. Uterus: normal. Bone marrow of shaft of femur yellow and normal. Heart: soft and pale, 11 oz., no fatty degeneration. Lungs: posterior portion of both mottled, with numerous small hæmorrhages about half a centimetre in diameter, but tissue just floats; no pleurisy.

*Microscopical examination.**—Liver: There is very extensive focal necrosis affecting about a third of each liver lobule, central portion; many of the cells are reduced to fragments. Diffuse, uniform, fatty metamorphosis, about one-third of the whole liver staining red with Sudan III. In the non-necrotic areas the fat is deposited in the cell in fairly large droplets, but the nucleus is often lateral and stains normally; in the necrotic areas, however, where much fat is also present some of the surviving cells are uniformly loaded with it, apparently a deposit of small droplets, but the nucleus is central and shows marked chromatolysis. There is a slight but definite portal cirrhosis and a slight increase in "bile-ducts," with localised infiltrations of lymphocytes and a few plasma cells, but no leucocytes. A few collections of amorphous green bile-pigment present in the canaliculi and smaller bile-ducts; some of the liver cells contained brown granules; there is a moderate number of small dense clusters of fine brown acicular crystals, most probably hæmatoidin crystals; they are best seen in thick sections and on the borders of the necrotic areas. These crystals are not tyrosin because they do not resemble it in colour or shape, neither do they give the characteristic pink reaction with a mixture of mercuric acetate, sodium nitrite, and acetic acid. Professor Ramsden demonstrated that the tyrosin which has been acted on by formalin—the fixative used in this case—*does* give the characteristic tyrosin reaction.[2] Lungs—*Hæmorrhagic* areas: Alveoli and bronchioles filled chiefly with erythrocytes; also small localised collections of polymorphs; a few catarrhal cells and traces of fibrin; a considerable amount of hæmatoidin pigment in certain areas—some being in crystals similar to the crystals in the liver; smaller blood-vessels contain unorganising red thrombi. *Non-hæmorrhagic* areas: Often congested, sometimes alveoli contain erythrocytes or occasionally leucocytes and a little blood pigment. There are a few dense clusters of Gram-positive diplococci, most probably pneumococci, and occasionally Gram-negative bacilli, probably colon group; these bacteria are most numerous in the hæmorrhagic areas.

The macroscopic and microscopic appearances strongly suggest that the hæmorrhages are due to the leaking of the capillaries, their distribution being determined by gravity, and they occurred at different dates, while the pneumococci invaded the damaged tissues *after* the hæmorrhage. Similar hæmorrhages have been described in spirochætosis (Stokes and toxic jaundice (Stewart).

Comments.

The patient's occupation, her short acute illness, and the appearances of the liver exclude *death* from chronic T.N.T. poisoning. Nevertheless, it is highly probable that T.N.T. absorbed before September, 1917, caused the slight cirrhosis—there is no history of alcohol or syphilis. On the other hand, death might possibly be due to acute T.N.T. poisoning or to latent T.N.T. poisoning, perhaps assisted by an infection or other poison. Professor Stuart McDonald reports a small epidemic of five cases of acute yellow atrophy in syphilitics, treated with "606" *plus* mercury, and suggests that some bacterial infection might have precipitated the liver disease. Finally, death might be entirely due to poisoning with arsenic, phosphorus, &c., to spirochætosis ictero-hæmorrhagica, sometimes called Weil's disease, or, lastly, to "acute yellow atrophy."

Poisoning with arsenic, phosphorus, &c.—Though none of the workers in the "cleaning" room had ever suffered from toxic symptoms, it was thought advisable to eliminate the possibility of death from arseniuretted hydrogen. Phosphorus might conceivably have been taken with suicidal intent. The appearances of the liver were quite distinct from that of a case of phosphorus poisoning I once saw in a girl who took a large quantity of rat poison and died in three days. Here the liver weighed 64 oz., was uniformly affected; the nucleus was in the centre of the liver cells and showed marked chromatolysis. Mr. Roberts, Liverpool city analyst, reported that "the liver was free from phosphorus, arsenic, and poisonous metals."

Acute T.N.T. poisoning.—This seems to be out of the question.

Latent T.N.T. poisoning.—Dr. W. J. O'Donovan describes a fatal case where toxic symptoms suddenly developed two months after leaving a T.N.T. factory. J. A. P. Barnes alludes to a woman who had been filling bags with T.N.T. and "left for a country holiday in apparently excellent health." Three days later she developed toxic symptoms and only recovered in three months.

A third remarkable case, described as latent T.N.T. poisoning, is that of a woman who "after two months' work in processes in the manufacture of T.N.T. was transferred to another department where she was employed in filling drums with benzol and toluol. Over seven months later she met with an accident—a spanner falling on her head. Toxic jaundice developed one week later and proved fatal in a fortnight." *The liver weighed 23 oz. and showed some "gamboge patches." The patient had been away from the T.N.T. room through illness on three occasions from 1 to 3 weeks. Once the doctor certified she was suffering from "laryngitis from nitrous fumes"; he also said, "as she could not stand the work" she was "removed to the benzol department where she worked for 7 months." During this time she kept "her clothes in the same cloakroom as the T.N.T. workers" but "apart from them."*[3] If death was due to T.N.T. poisoning it is not conclusively proved that it was "*latent.*" Dr. Legge informs me that benzene is

[1] Through the courtesy of Mr. Foggo I visited the factory in company with Dr. Mary Deacon, medical officer to an adjoining munition factory.

* Micro-photographs will appear in a later issue.

[2] The writer has examined, macroscopically and microscopically, the liver in two cases of acute yellow atrophy before the war—for one see Bradshaw, Brit. Med. Jour., 1901, vol. ii., p. 1587. One case of acute phosphorus poisoning and two of toxic jaundice due to T.N.T.

[3] The information between the two asterisks was obtained from the inquest report kindly provided by the factory inspector.

certainly toxic, both in acute and chronic form. In the acute, it produces rapid unconsciousness; in the chronic, aplastic anæmia precisely like that of T.N.T., with terminal symptoms of purpura hæmorrhagica. No cases, however, of "*jaundice or atrophy of the liver*" have been recorded either in Great Britain, the United States, Austria, or Sweden.

My case differs greatly from this, notably in the absence of symptoms when exposed to T.N.T., the longer "latent"? period—viz., 9 months—the short terminal illness, and the different liver changes. Latent poisoning is almost excluded.

Bacterial infection most probably did not precipitate the illness, for no bacteria were demonstrated in the liver and the spleen was small and firm. The pneumococci almost certainly invaded the lungs after the hæmorrhages had occurred, though they may have caused the terminal pyrexia.

Spirochætosis.—Immediately after the post-mortem many films from the liver and spleen—but, unfortunately, not the kidney—were examined by the dark ground for spirochætes, but the results were negative. A stale specimen of urine obtained post mortem was not injected into guinea-pigs owing to the difficulty of obtaining them.

In the fatal cases of this disease recently described in our Army, the liver has sometimes been slightly enlarged, though in the majority there was "an absence of any definite anatomical changes." In two cases, however, described by Sir Bertrand Dawson and W. E. Hume the liver cells were "dissociated" and "many markedly enlarged," but there was *no necrosis*, only a *little* fat, and the cellular infiltration of the portal areas contained *leucocytes* as well as lymphocytes. Thus, apart from the fact that the liver in our case was diminished in size, the pathological changes are markedly different. Careful inquiries, moreover, showed that the patient had seen no soldiers from abroad for a long period.

"*Acute yellow atrophy*."—The available evidence renders it probable that the patient died of "acute yellow atrophy"—whatever that is. The comparatively slight diminution in the size of the liver, the absence of red atrophy or of regeneration, and perhaps the excessive amount of fat, may be explained by the short duration of the illness.

Urine reaction.—If death was not due to T.N.T. poisoning the presence of the T.N.T. urine reaction requires explanation, especially as such reaction is apparently always absent in T.N.T. workers when toxic jaundice supervenes. The specimen was therefore sent to Professor Benjamin Moore, who reported that there was no T.N.T.; the misleading pink was due to some drug, e.g., phenolphthalein. On inquiry I found the patient had never taken phenolphthalein either before or after admission to hospital, but rhubarb and soda had been given before. My assistant, Dr. A. L. Robinson, indicated that rhubarb should give the test.

Dr. Matthews kindly administered a little rhubarb and soda for two or three days to four hospital patients. Their urine when tested by Webster's method gave a pink reaction, or pink-purple if strong—three of the urines were tested before administering rhubarb, with negative results; this colour appears to be due to chrysophanic acid or its derivatives.

The T.N.T. reaction is described as "purple" in the official communication,[4] and as "pink" in the Medical Research Committee Report, No. XI.—the Causation and Prevention of Tri-nitro-toluene (T.N.T.) Poisoning, p. 17.

Summary.

A young female munition worker, previous health always good, died suddenly of acute toxic jaundice (?) nine months after leaving the T.N.T. filling room. The liver, however, was much larger, more fatty, and more necrotic than in T.N.T. poisoning, and regeneration was absent. Poisoning with phosphorus or arsenic was excluded; latent T.N.T. poisoning with or without bacterial infection was almost excluded; spirochætosis ictero-hæmorrhagica is probably excluded. Death is therefore probably due to "acute yellow atrophy"—whatever that is. The pseudo T.N.T. reaction in the patient's urine was evidently due to rhubarb.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF INTRAPELVIC OSTEOMA NECESSITATING CÆSAREAN SECTION.

BY VIOLET I. RUSSELL, M.B., B.S. LOND.,
RESIDENT MEDICAL OFFICER, QUEEN CHARLOTTE'S LYING-IN HOSPITAL.

AN osteoma arising from the pelvis is a sufficiently rare complication of labour to be worthy of record. The chief interest of the following case consists in its illustration of the importance of a routine examination of the pelvis during pregnancy in a primigravida; the tumour was causing no symptoms and might easily have remained undiagnosed until labour was advanced, when the prognosis for mother and child would have been much less favourable.

The patient, aged 19, was first seen when 28 weeks pregnant by Dr. Frances Huxley in the antenatal department of Queen Charlotte's Hospital. External pelvic measurements were approximately normal—interspinous 9 in., intercristal 10 in., and external conjugate 7¾ in. The fœtus was presenting by the vertex, the head being movable above the pelvic brim. On vaginal examination a bony tumour was felt occupying the left side of the pelvis; it was causing no symptoms. Mr. Clifford White examined the patient under anæsthesia when the osteoma was found to arise by a stout pedicle from the inner surface of ischium at the level of the acetabulum. It measured about 1½ × 2 in. in diameter, was uniformly hard, irregular in outline, and obviously proved an insuperable obstacle to delivery by the natural passages.

Cæsarean section was performed at term by Mr. Clifford White and a female child weighing 6 lb. 10 oz. was delivered. The internal relations of the growth were then defined. It was felt projecting between the layers of the broad ligament on the left side and was crossed by the left ureter; the origin of the tumour was in close relation with the bifurcation of the left common iliac artery, the external iliac vessels passing in front of growth and the internal iliac artery lying behind it.

Convalescence from operation was uneventful, and mother and child were discharged in good condition. The tumour has shown no increase in size since patient has been under observation and has never caused any symptoms.

I have to thank Mr. Clifford White for his kind permission to publish the case.

PNEUMOCOCCUS ARTHRITIS; VACCINE TREATMENT; RECOVERY.

BY C. E. CAMPBELL-HORSFALL, M.B., CH.B. VICT.

THE following case is of interest: first, because its commencement was very unusual—there had been no previous illness, nor was any focus of infection found; secondly, the method of treatment led to prompt recovery.

The patient, a middle-aged woman, was seized with pain in right knee; there was no history of injury or previous illness, and the condition was treated as a simple synovitis. The condition, however, did not subside, and a further diagnosis of rheumatoid arthritis was made and treatment carried out. No improvement took place, and gradually other joints were implicated. After several months' futile treatment she came under my care. At this time patient was utterly helpless and unable to move; even the upper extremities could only be moved with great pain. She was in a state of profound sepsis with typical septic temperature, skin a pale earthy colour, and marked anæmia of mucous membranes. Practically all joints were involved, the most marked changes being in knees, ankles, wrists, and shoulder-joints. The phalangeal joints were swollen, painful, and spindled-shaped. No reddening of any joints. Knee-joints distended with fluid; appetite poor.

I advised aspiration of knee-joint for diagnostic purposes. This was done and a bacteriological examination made of the fluid, this latter being a thick turbid material, greyish-yellow in appearance. On culture this showed a mixed infection of pneumococci and streptococci. A vaccine was made and treatment begun. She was kept in bed, given the maximum of fresh air, her bed being moved out on to a balcony when the weather was suitable. Her improvement as soon as vaccine was started was remarkable. Temperature steadily decreased, appetite returned, skin and blood condition improved, and pain abated. As soon as temperature became normal gentle message of limbs was commenced but joints were left severely alone at first. Later the latter were rubbed and moved. Progress was uninterrupted, and from an apparently dying woman she was restored to her former health, and at the present time it is impossible to realise that she had ever been so ill. She has free movement in all her limbs and can close her hands with ease.

The majority of pneumococcus arthritis cases are surgical and often one or two joints are affected. Surgical treatment in this case with a multiplicity of joints affected, even if successful, would have been very tedious, and much disuse of joints would have ensued. The termination of this case with its perfect recovery emphasises the necessity of having the joint fluid examined in every case of multiple arthritis when practicable. I can find no record of any case treated with a vaccine with such a pleasing result.

My thanks are due to Professor Walker Hall, of Bristol, who examined the fluid for me and prepared the vaccine.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

AT a general meeting of the Fellows of the Royal Society of Medicine on Tuesday, Oct. 15th, Sir RICKMAN GODLEE, the retiring President, introduced the new President, Surgeon Rear-Admiral Sir HUMPHRY ROLLESTON, and invested him with the President's badge (the gift of the late Sir Edward Sieveking, M.D., former President of the Society), and with the President's gold master-key (the gift of Mr. J. Y. W. MacAlister, the secretary). Sir Humphry Rolleston then took the chair and briefly thanked the Fellows for the honour of his election, and asked for the sympathy and support of all of them in the discharge of his duties during what might prove to be a very trying period. The ordinary business of the meeting was then proceeded with and a number of new Fellows upon ballot were elected.

On this occasion there was a pleasing innovation before the meeting, which, it is hoped, will become the custom. Tea was served in the President's private room, and Sir Humphry Rolleston received the Fellows who had come to attend the meeting; in this way becoming personally acquainted with those whom he had not previously met, and renewing many old acquaintances.

COMBINED SECTIONS OF MEDICINE, PATHOLOGY, AND EPIDEMIOLOGY.

Encephalitis Lethargica.

THE occurrence in the earlier part of this year of numerous cases characterised by lethargy, asthenia, and paralysis, usually of the cranial nerves, aroused widespread interest at the time, and has led to a large amount of research. At a joint meeting of the Medical, Pathological, and Epidemiological Sections of the Royal Society of Medicine held on Oct. 22nd the results of these investigations were discussed at length. A brief summary of this discussion follows, the detailed report being reserved for a later issue.

The *stages in the development of our knowledge* of the disease may be stated thus: After a short period, during which the striking lethargy led to the somewhat sensational diagnosis of "botulism" the failure to find the *Bacillus botulinus*, together with the discovery of areas of perivascular infiltration in the central nervous system, caused many to assume that the disease was acute poliomyelitis of the cerebral type occurring in epidemic form. This assumption was all the more natural because the observers of epidemics of the latter disease had laid special stress on the protean character of the symptomatology, Wickman describing no less than seven types. At an early stage, however, clinical observers began to note that the disease possessed a characteristic symptomatology which differed from that of acute poliomyelitis. The extensive investigations which have since been carried out appear from the discussion to have led to the almost unanimous adoption of the view that the disease is not acute poliomyelitis but is sui generis, with a symptomatology of its own, varying according to the precise areas of the central nervous system affected in individual cases, with a characteristic pathological picture and definite epidemiological peculiarities.

The *onset* is frequently sudden, but more often there is a prodromal stage lasting a few days, with lassitude, headache, and sometimes vomiting of the cerebral type. The patient then passes into a lethargic condition, from which, however, he can be roused and in which he remains conscious of what is passing around him. Nocturnal wakefulness with or without delirium is not uncommon. There is general asthenia, with definite local paralysis, particularly of the ocular muscles, the muscles of the face, and, less frequently, of the pharynx, giving rise to strabismus, nystagmoid movement of the eyes, dysarthria of speech, dysphagia, and a mask-like expression. The onset of the local palsies is described as "wandering," first this, then that, group of muscles being affected. The headache, vomiting, delirium, dysarthria of speech, occasional katatonia, and incontinence have caused individual cases to be initially diagnosed as "functional," G.P.I., or tuberculous meningitis. The course of the disease is variable; in some instances death takes place within a few days of onset through paralysis of respiration, but in most recovery has ensued after an illness lasting several months.

The typical *pathological lesions* are hæmorrhagic foci with lymphocytic infiltration of the small vessels. They are found mainly in the midbrain and pons, but may occur anywhere in the cerebrum, cerebellum, or spinal cord. Colonel F. W. Mott (who also communicated the results of investigations carried out by Professor Marinesco) describes these lesions as differing markedly from those found in acute poliomyelitis, particularly in the rarity of neuronophagia and in the hæmorrhagic nature of the lesions. He found no organisms. The cerebro-spinal fluid shows lymphocytosis in some cases, in others none; the discrepancy may be explained by the fluids having been examined at different stages in the disease. Blood is found frequently; its presence may be considered characteristic of acute cases of the meningeal type.

The *epidemiology* of the disease presents features which distinguish it clearly from acute poliomyelitis. As a result of the findings of the Local Government Board inquiry held by Sir Arthur Newsholme, Lieutenant-Colonel S. P. James reported that the disease occurs at all ages and shows no preference for the young; its seasonal incidence shows a maximum in the spring, whereas acute poliomyelitis is at its height in August and September; the distribution of cases in England and Wales shows no correlation between the two diseases. The report of the Local Government Board will be issued shortly. It is to be hoped that the compulsory notification of Encephalitis lethargica will be as successful in adding to our knowledge as it has been in other instances. So far research has chiefly resulted in clearing the ground, and practically everything constructive remains to be done, particularly in regard to treatment.

SOCIÉTÉ DE BIOLOGIE, PARIS.

THE following is a summary of the papers read at a meeting of this society held on Oct. 12th:—

DUJARRIC DE LA RIVIERE: Bacteriological Diagnosis of Influenza.

Prélever 10 cm.c. d'urine aseptiquement, ensemencer en milieu eau peptonée (sang de poule). Alors que les autres procédés échouent, la présente technique décèle le B. de Pfeiffer dans presque tous les cas.

R. J. WEISSENBACH: A New Medium for Differentiating the Enterococcus from Certain Streptococci.

Les streptocoques non hémolytiques se comportent comme les streptocoques hémolytiques quand ils sont ensemencés en eau peptonée glucosée, additionnée de bile. Alors que l'entérocoque, après 18 à 24 heures d'étuve à 37° cultive abondamment dans ce milieu, les streptocoques pyogènes hémolytiques et non hémolytiques ne donnent naissance à aucune culture en 18, 24 heures et au-delà. A défaut du pouvoir hémolytique, qui constitue dans la pratique un des meilleurs caractères différentiels entre l'entérocoque et la variété hémolytique du streptocoque, la plus fréquemment en cause en pathologie humaine, le résultat de l'ensemencement en eau peptonée glucosée à la bile constitue pour le streptocoque hémolytique, un excellent élément de différenciation.

GERARD: Thermal Instability of Syphilitic Antibodies.

En évaluant les limites maxima de déviation du complément produites par un même sérum chauffé à 56° et non chauffé, on s'aperçoit de la constance thermolabilité des anticorps syphilitiques. Le pouvoir de déviation pout être abaissé des trois quarts. Conclusion: Associez toujours dans les Wassermann les deux méthodes au sérum chauffé et non chauffé. Réduisez, dans la méthode complète, le temps de chauffage à 56° pour destruction du complément à un quart d'heure au lieu du temps classique de une demie-heure.

LATAPIE: Experimental Influenza.

Les bacilles de l'influenza restent vivants pendant 4 mois dans les abcès provoqués expérimentalement chez les cobayes et 22 mois en sac de collodion chez les mêmes animaux. Chez une chèvre soumise à l'immunisation pendant onze mois, le sérum se montre même curatif: des cobayes inoculés avec une dose plusieurs fois mortelle de microbes dans le péritoine et devant mourir en moins de 24 heures pouvaient être préservés par du sérum injecté dans les veines trois heures avant la mort. L'auteur met en garde contre la toxicité du sérum récolté peu de temps après l'injection des microbes; passé le délai de trois semaines depuis la dernière injection, cette toxicité n'existe plus.

M. NICOLLE: Restitution of Agglutinability.

Quand les pneumocoques et les gonocoques ont perdu leur agglutinabilité, on peut la leur restituer en les traitant par l'acide chlorhydrique en les chauffant, enfin en les neutralisant par la soude.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, QUEEN-SQUARE, LONDON.—Founder's Day will be celebrated on Monday, Nov. 4th, when the wards will be open to inspection from 3 to 6 P.M.

Reviews and Notices of Books.

The Evolution of National Systems of Vocational Re-education for Disabled Soldiers and Sailors. By DOUGLAS C. MCMURTRIE. Washington, U.S.A.: Federal Board for Vocation Education. 1918. Bulletin No. 15 (Re-education Series No. 3). Pp. 265.

As the title denotes, this report traces the evolution of the systems of vocational re-education for disabled soldiers and sailors in the countries where such systems exist. The material for the sections relating to France and Belgium has been prepared by Miss G. G. Whiteside, to Great Britain by Dr. J. C. Faries, to Italy and Germany by Miss R. Underhill, and to Austria by Mr. A. Gourvitch. In the introduction Mr. McMurtrie emphasises the part played in the evolution of these systems by the Belgian trade schools for crippled victims of industrial accidents. The obvious corollary, the extension of the facilities for disabled soldiers to industrial cripples, has recently been suggested in the British lay press. As Mr. McMurtrie points out, the dictates of national gratitude and national economy coincide as to the need for systems of re-education. As the result of a review of the various systems he has drawn various conclusions. He holds it to be axiomatic that a man should be given his course of training in a locality near his home. He is not in favour of compulsory re-education; the unwilling pupil learns but little. "If a competent visitor has been in touch with the man's family during his absence at the front the members of the home circle can be easily convinced of the wisdom of his re-education; this will make all the simpler persuasion of the man himself." The choice of a particular trade must meet with the full approval of the soldier himself; Mr. McMurtrie would allow the man, within reasonable limitations, to change to another trade if the subject prove definitely distasteful. To persuade him to undertake training the disabled man should be informed of the progress of men with similar physical handicaps, but this information must be accurate and not relate to freak successes. "It would seem inadvisable to train a man for an occupation which he can pursue only by means of specialised apparatus adapted to individual motor limitations imposed by his deformity. While a badly crippled man may be taught to operate a lathe with special treadles his opportunities for employment will be precarious." Many of those interested in the problem will not agree with Mr. McMurtrie in this conclusion, especially if State workshops be provided for men with severely crippled arms. The American Red Cross Society, however, appear to be more optimistic than we are as to the possibility of industrial firms providing work for this class of man. An interesting commentary is that the training provided must be thorough; there would be an unjustified disturbance of the labour market and its wage-standards if a school thrusts into a trade, as professedly skilled operatives, a crowd of under-trained men. As regards employment disabled soldiers must be considered as a special class. The transition from military to civilian life which takes place on a man taking up his first job is a more radical step than the change made when the civilian employee goes from one position to another. For this reason Mr. McMurtrie advocates the appointment of specially trained employment officers for placing and following up disabled men.

The section on the work in Great Britain contains some racy comments on our ways of doing things, but pays a tribute to the system which has ultimately been evolved. Although the writers of the report do not make the comment, we have something to learn from Germany in our treatment of one-armed men. In no less than 14 trade schools, scattered over the various German states, special courses are held for one-armed men. After preliminary instruction of about six weeks in the ordinary acts of every-day life, and a course of left-handed writing, if necessary, the men take up trade training. Again, in the larger matter of simultaneous medical treatment and re-education we are behind other countries. In Germany re-education is undertaken by civilian care committees working in military hospitals. The section on France tells us that the schools which admit soldiers only when completely cured have considerable difficulty in obtaining pupils, while the schools at Montpellier and Bordeaux have found their usefulness increased since they have been linked up with hospitals. Coöperation between hospital and school has from the beginning been carried out successfully at Saint Maurice, the Grand Palais, and Maison Blanche. Dr. Kresser, head of the school at Maison Blanche, writes: "The best recruiting agency for the schools is the example of the man who works at a trade during the day and who, on his return to his pavilion in the evening, tells his companions what he has been doing and what he has earned." The excellent results obtained at the South African Military Hospital, Richmond Park, show the value of coincident medical treatment and vocational re-education. The percentage of disabled men who undertake training is extremely high—over 90. If the commanding officer of the hospital considers a man will not become fit for further military service no time is lost in commencing his re-education. The training does not stop when the man is discharged from hospital; he is accommodated at a hostel and continues his course; during this time the men continue to wear their uniform and remain under military discipline.

An appendix contains a comprehensive bibliography of the subject. As a review of the systems of re-education the report is unique; it cannot fail to be of the greatest value to the workers in the United States of America for whom it was written.

Clinical Diagnosis: A Manual of Laboratory Methods. By JAMES CAMPBELL TODD, Ph.B., M.D., Professor of Clinical Pathology, University of Colorado. Illustrated. Fourth edition, revised and reset. London and Philadelphia: W. B. Saunders Co. 1918. Pp. 687. 14*s*.

THIS work is a practical manual which treats of the more important methods employed in the investigation of those problems of diagnosis which are now customarily submitted to the clinical laboratory. In reviewing earlier editions of the book[1] a favourable opinion was expressed as to its merits, and practical use of this work in the reviewer's laboratory has confirmed this opinion. The methods selected are usually good and the directions clear and precise, while the deductions drawn from the results of the investigations are judicious.

A considerable number of additions and alterations have been made in the present edition which have improved it and brought it up to date without undue increase in size or price. On the other hand, some methods have been omitted and these include Abderhalden's protective ferment reaction to which exception was taken in the review of the 1914 edition. Important additions are to be found in the section on blood examination. These include the methods for recognising blood by spectroscopic and chemical means, for the vital staining of blood cells and for testing the resistance of red cells. The methods used in the selection of blood for the purposes of transfusion and for matching bloods are now given, together with a short account of the theoretical basis for these methods. The plan devised by Bass and Johns for facilitating the search for malarial parasites in the blood by concentration is described and recommended. An illustration shows the satisfactory results obtained. In the examination of cerebro-spinal fluid two new tests are proposed—Lange's colloidal gold test and the "mastic test"—for the purpose of distinguishing pathological changes in the central nervous system, especially those caused by syphilis. Changes and simplifications in the technique for carrying out the phenol-sulphone-phthalein test of the functional activity of the kidneys are described, and further details are given as to the clinical interpretation and value of the test. There are many other additions, including Schick's test for immunity to diphtheria, Craig's method for the complement deviation test for tubercle, the estimation of urobilin in fæces, which is useful in the diagnosis of pernicious anæmia, and of amylase in fæces, useful in suspected pancreatic disease.

The illustrations have always been an important feature of this book, and in the present edition there has been a marked improvement effected by substitution for the less satisfactory plates and figures of better ones and considerable additions of new figures, among which may be mentioned a representation of Curschmann's spirals, as seen in the usual naked-eye examination of asthmatic sputum, and one of *Entamœba gingivalis*. The production of the book leaves little to be desired.

[1] THE LANCET, April 10th, 1915.

THE LANCET.

LONDON: SATURDAY, OCTOBER 26, 1918.

Our Present Knowledge of Epidemic Catarrh.

EPIDEMIC catarrh has once again become pandemic in character. Reports are being daily received of its prevalence all over the world, some of them of a highly alarmist nature. The issue of an authoritative Memorandum on epidemic catarrh, including influenza, by the medical officer of the Local Government Board is therefore peculiarly opportune, especially as the document has been sent to all the local authorities in the country, with a suggestion to the health officer to prepare precautionary instructions for use in his district. After discussing certain statistical facts in relation to the deaths from respiratory diseases in general, and alluding to the micro-organisms generally associated with a "common cold," Sir ARTHUR NEWSHOLME reminds us that influenza has been identified historically for several centuries past, appearing and causing great havoc in many countries at intervals which have been so prolonged as to create the impression on its reappearance that a new disease had emerged. Dr. F. G. CROOKSHANK has, in fact, given the title of "The Story of a New Disease" to the Chadwick Lectures which he is delivering, and Sir RICHARD DOUGLAS POWELL, presiding at one of these lectures, emphasised the remarkable coincidence between epidemics of influenza and outbreaks of poliomyelitis, a coincidence which should lead to a more careful scrutiny of influenza as a syndrome of many diseases yet to be accurately defined and demarcated. Dr. W. COLLIER, of Oxford, calls attention in our correspondence columns to certain unfamiliar features in the cases under his observation. A study of Dr. FRANKLIN PARSONS'S classical reports to the Local Government Board on the pandemic of 1889–92 shows the impression then prevailing of a novel disease, although 43 years earlier (1847–48) and in 1803, 1833, and 1837–38 epidemics of influenza occurred in this country. Dr. W. H. HAMER has adduced evidence of the same experience in even earlier literature.

The difficulty of defining influenza is, of course, great, its most characteristic feature being its occurrence at long intervals as an epidemic which spreads rapidly from country to country and from continent to continent, and which affects a much higher proportion of the total population than any other known infectious disease. The Memorandum of the Local Government Board takes the view that the question whether Pfeiffer's bacillus is the specific cause of influenza is still an open one. Unfortunately, no specific agglutination tests are yet available in connexion with this micro-organism. That it causes much of the mischief produced by the disease is proved by its frequent presence in large numbers in immediate relation to minute lesions occurring in the lung. It should be noted, however, that the Pfeiffer bacillus is occasionally discovered in bronchial secretions when there is no suspicion of influenza; but, on the other hand, the bacillus has not been found, or has only been discovered in a very small minority of the total cases, in a considerable number of outbreaks indistinguishable clinically from influenza. The Memorandum itself does not state whether this is the case in the present epidemic, but information from several sources suggests that Pfeiffer's bacillus has not often been identified. Failure to isolate the bacillus may be due in certain instances to want of a suitable culture medium, as was pointed out recently in our columns by Dr. JOHN MATTHEWS. In outbreaks in which this bacillus is absent the *M. catarrhalis*, the pneumococcus, or a hæmolytic streptococcus has generally been the predominant micro-organisms. It is difficult, therefore, to establish an accurate bacteriological test for influenza, and on account of its multiform clinical symptoms a definite diagnosis is not always easy. This fact stands greatly in the way of any specific treatment of the pandemic malady, although much attention has been given to this aspect of the problem. On another page of this issue of THE LANCET an account is given of a Conference held at the War Office to discuss the utilisation of vaccine for the prevention and treatment of influenza, and a précis of the conclusions arrived at by the bacteriological experts who attended this Conference is embodied in an appendix to the Local Government Board's Memorandum. At this Conference it was unanimously agreed that inoculations with a suitable vaccine might be expected to be of value, although there is at present no vaccine on which dependence can be placed to give immunity against influenza.

General precautions, fortunately, are on a sounder footing, and the Memorandum of the Local Government Board rightly points out that control over the disease is only practicable by the active coöperation of each member of the community. The measures suggested are largely such as a sensitive hygienic conscience would direct. Most persons attacked by influenza do not recognise for several days the serious nature of their illness, and it is probable that infection is chiefly spread during the earlier stages. This, and the fact that one attack does not appear to confer any great degree of immunity against further attacks, render the application of preventive measures far from easy. In view of the difficulty in securing early and decisive diagnosis, especially in connexion with the milder cases for which medical guidance is not obtained, notification cannot be recommended as likely to be of practical use. The isolation of all persons suffering from fever, with or without catarrh, is recommended in the Memorandum; but, however desirable such a course might be, it would be difficult to accomplish on a large scale. As infection is probably conveyed in part by the fine spray of mucus ejected in the act of coughing or sneezing, it is advised that a handkerchief should be held before the mouth at such times in order to intercept the droplets of mucus, and that the handkerchief should afterwards be boiled. Disinfection of premises after

influenza is not recommended, but a thorough washing and cleansing of rooms and their contents and washing of articles of bedding or apparel are desirable. The familiar advice is given that the patient should go to bed on the first onset of the symptoms and remain there till all fever has gone. The only safe rule is to regard all catarrhal attacks and every illness associated with rise of temperature as infectious, and to adopt at once precautionary measures. The wet cleansing of all infected places is important. Indiscriminate spitting is dangerous, and prolonged mental strain or over-fatigue, and still more alcoholism, are all conditions which predispose to attack. As a prophylactic measure gargling the throat with a solution of 1 in 5000 permanganate of potassium in water containing 0·8 per cent. of common salt night and morning is useful. It is pointed out that sanitary authorities have power, with the Local Government Board's sanction, to provide nursing assistance for those who are unable to obtain it for themselves. The possible public provision of a prophylactic spraying apparatus, such as is used in the Army, is considered. The view is expressed, however, that the "spray room" cannot yet be regarded as reducing for certain the incidence of attacks in exposed persons, and unless precautions are taken to separate patients from healthy persons it may even be the means of disseminating infection. The final, and probably the most important advice of all is that bedrooms and living rooms should be constantly flushed with fresh air, and that overcrowded rooms and places of amusement should be avoided. The aggregation of large numbers of persons in one room, especially for sleeping, is dangerous when catarrhs are prevalent, even though the floor space for each person may appear to be adequate.

Sir ARTHUR NEWSHOLME'S Memorandum presents us with an admirable summary of the outstanding features of influenza epidemics, so far as they have been ascertained, and of the prophylactic measures to be employed in connexion with that disease. It helps us also to realise how little is yet known about the epidemic catarrhal conditions which are the cause of so much illness and death, and emphasises the urgent need for further investigation.

Juries on Trial.

BY the Juries Act, 1918, which came into force on July 30th the right to a jury is limited in civil cases during the war and for six months afterwards. Under this Act every "action, counterclaim, issue, cause or matter in the High Court of England requiring to be tried" is to be tried by a judge sitting alone. This does not affect any power to order a trial by two or more judges, or a judge with an assessor, or any such special tribunal as heretofore. It is also subject to the proviso that in cases in which fraud is alleged, or where the claim is in respect of libel, slander, malicious prosecution, false imprisonment, seduction, or breach of promise of marriage, either party is entitled to have a jury upon applying for one in the prescribed manner. Also in other cases than the above a judge may order the trial to be with a jury on the application of a party, if the case appears to him to be more fit for trial with than without one, and a jury is to be granted, if applied for, in certain contested matrimonial causes and in certain causes in the Probate Court. Trial without a jury is ordered upon practically similar terms in county courts and other courts of inferior jurisdiction. This may seem a more sweeping change than it really is. The general public, familiar with the phrase that the jury is the palladium of liberty, and interested mainly, as far as civil cases are concerned, in those of the more sensational kind, does not realise how much the jury has been dispensed with. In the Courts of Chancery and Admiralty there is never a jury, and in a great number of important commercial causes, as well as in the majority of divorce cases and of trials in the county court, there is none either; and though criminal cases are not affected by the new Act, very many more criminal charges are disposed of without a jury than with one. The tendency to diminish the number of trials by jury is not a new one. In the Common Law courts, since the Judicature Acts were passed towards the end of the last century, many cases, besides the commercial causes already referred to, are now heard by judges alone for which juries would formerly have been necessary, and no one has complained. It would seem, therefore, as if the jury, once a bulwark of the people against the aggression of the Crown or the executive or any other oppressor, was coming to be regarded as a cumbrous survival.

Few will deny that without a jury many trials would be shorter; while men unwilling to serve, unwilling to give full attention to, or, perhaps, unable to understand the evidence may be present on a jury and prevent justice being done. Judges are human it is true, and liable to human sympathies and prejudices, but so in a greater degree are juries; and although sympathy may be an excellent thing in individuals it can lead to absolute injustice in 12 men assembled to try, not whether a plaintiff has suffered and the defendant *can afford to pay* compensation for that suffering, but whether the defendant is legally responsible for that suffering, so that in justice he *ought to pay* for it. Juries also fail sometimes to arrive at unanimous verdicts, or members of them have to be cajoled by their fellows into agreement which is contrary to their honest judgment. Either happening is undesirable, and the former leads to delay and increased expense for the parties to the trial. It may be observed also that it is after long trials contested at great expense that disagreement on the part of the jury most frequently occurs. The action against the British Medical Association recently tried by Mr. Justice MCCARDIE may be referred to as a case in point. This was one of those long-drawn-out and hard-fought trials, in which sympathisers with the British Medical Association in its effort to maintain its ethical standards might have found themselves on a jury pitted against others with preconceived views antagonistic

to doctors, and hence determined from the first to regard the plaintiffs as men unjustly oppressed, for whom no damages could be too ample. A disagreement in such circumstances would have been in no way surprising had the decision been left to a jury, and this would have been very expensive to both parties; a verdict for the plaintiffs, such as Mr. Justice MCCARDIE found, but with damages of unjust and disproportionate magnitude, would have been a second likely issue. We do not know whether an appeal may follow in this case or whether the fact of no appeal being entered will indicate the acquiescence of the losers with the learned judge's statement of the law and his application of it to the facts before him; but in ordinary circumstances in libel cases we believe that a jury is unnecessary for the assessment of damages and that a fairer and more satisfactory result may be arrived at without one.

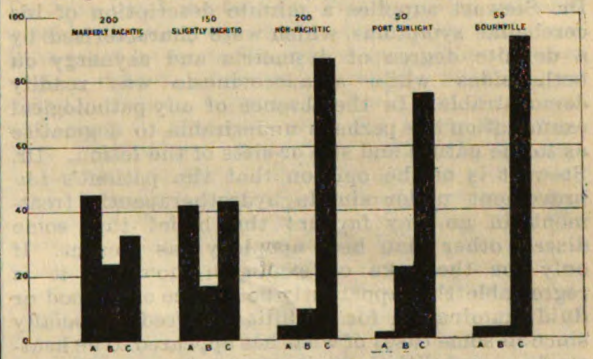
Dr. F. J. WALDO, the coroner for the City of London and the Borough of Southwark, appears to have been questioned recently by a juryman as to why he was continuing to summon juries to sit at inquests when other coroners were availing themselves of the Act above referred to and dispensing with their services. In making a reply to this question at the close of an inquest Dr. WALDO explained that a discretion was allowed to him, in the exercise of which he was guided by what he believed to be principles of public policy and usefulness. At inquests in the course of which it appeared that murder or manslaughter was to be suspected, he was still obliged to summon a jury, and according to his experience in the majority of the inquests that he held questions of culpable negligence were likely to arise. This was due to the fact that a large number of the deaths which he inquired into were caused by accidents in factories or elsewhere, when the presence or absence of negligence was the essential fact to be ascertained. In such cases he believed that the public interest was best served and the public confidence retained by the course which he followed. Here we agree with him, while we congratulate him on being able to refer in such complimentary terms to the quality of the juries in the areas for which he is coroner—men, he described them, who are well able to follow and weigh the evidence laid before them. Not all juries are as intelligent or as competent to discharge their functions as those of the City and of Southwark, but such busy areas as these are even less able than others to supply persons who can be spared from their usual avocations. It seems likely to us that coroners will have to be prepared for a continuance of conditions imposed in view of the new and unprecedented state of affairs which has recently prevailed, and we have no doubt that they will be fully equal to the occasion. They can obtain for their guidance in all difficult cases the evidence of expert pathologists as well as that of medical practitioners equipped by modern training, and they are themselves either men with medical qualifications, or who, in the practice of their previous professions, as barristers or solicitors, have learnt to grasp and to appreciate the essential points in scientific and other evidence laid before them. The medical witness has not always been handled with courtesy or intelligence by coroners, but it is the uneducated juryman whom he really fears and whose disappearance he will not regret.

Annotations.

"Ne quid nimis."

RICKETS AND FRESH AIR.

THE most striking chart in the Medical Research Committee's study of the causation of rickets[1] is that dealing with the effect of air and exercise. For the purpose of this inquiry Miss Margaret Ferguson divided the children whose social and economic state she was investigating into (A) those who were not taken out at all; (B) those who were taken out a little; and (C) those who were taken out sufficiently. In the series of 200 markedly rachitic Glasgow children, over 40 per cent. had not been taken out into the fresh air at all, while in a similar series of 200 non-rachitic children only 4 per cent. had been confined indoors. These observations are made graphic on the chart which we reproduce here, along with a comparison with groups of children at Port Sunlight and Bournville. The conclusion drawn from these observations by Professor Noël Paton and Dr. Leonard Findlay, reviewing the evidence (the report states) "as a small



jury," is that inadequate air and exercise seem to be potent factors in determining the onset of rickets. The report frankly admits the possible fallacies in any purely observational method of inquiry, and suggests that the significance of "lack of air and exercise" in causing rickets can only be determined in terms of specific physiological processes by methods of experiment. The weight of evidence in Miss Ferguson's social inquiries is against a close association between deficient diet and the rickety condition, whereas in Dr. Edward Mellanby's study of experimental rickets in dogs (summarised in the Research Committee's last annual report) accessory factors in food appeared to play a large part. These are matters of first importance to large masses of our industrial population, especially under war-time conditions, and the Medical Research Committee cannot do better with the funds of the National Health Insurance than devote them to the elucidation of such problems.

CEREBELLAR SYNDROME FOLLOWING HEAT-STROKE.

WITH our various extensive campaigns in tropical and subtropical zones heat apoplexy or heat-stroke (thermic fever, siriasis) has come into prominence as a cause of incapacity, and the toll it has already taken of some that the profession could ill spare is added reason for its careful investigation. In the current number of the *Review of Neurology and*

[1] A Study of Social and Economic Factors in the Causation of Rickets. With an introductory historical survey. Special Report Series, No. 20. 1918. Price 2*s*.

Psychiatry is a paper by Dr. R. M. Stewart, describing in detail the clinical phenomena in a case the sequelæ of which were peculiar and perhaps unique.

The patient, a soldier, aged 32, was in Egypt in October, 1914, and after a 26 hours' journey by train with his regiment marched to barracks, a distance of about a mile. The men wore sun-helmets, thick serge uniforms, and carried their full equipment on their backs. The temperature was 109° F. in the shade. Shortly after his company had been dismissed he was found lying outside a barrack-room, deeply unconscious. He was at once admitted to hospital, where he was seen to be comatose, flushed, with stertorous breathing and with occasional irregular clonic epileptiform movements. His body temperature was 109·2°. For a week it remained high, varying between 100° and 103°. During this time he was profoundly unconscious and nasal feeding was resorted to. Some ten days from the onset he began to show signs of recovery, but his sentences were mere gibberish; he was childish, and incontinent of urine and fæces. By Dec. 10th he had improved considerably and sphincter control was normal. He was then noted as having developed a spastic paresis of the legs, with marked ataxia of all four limbs. A careful examination on his admission to a military hospital in England in April, 1915, showed that the condition was one of spastic paraplegia, with double extensor response, lateral nystagmus, extreme dysarthria, involuntary movements of the limbs more or less athetoid in type, ataxia in voluntary movements; in addition he was childish and distinctly emotional, laughing in a silly manner.

Dr. Stewart supplies a minute description of his cerebellar symptoms, which were characterised by a definite degree of dysmetria and asynergy on both sides while adiadococinesia was readily demonstrable. In the absence of any pathological examination it is perhaps undesirable to dogmatise as to the nature and site or sites of the lesion. Dr. Stewart is of the opinion that the patient's improvement under simple hydrotherapeutic treatment in no way favours the belief that some disease other than heat apoplexy was present. If only for the sake of exclusion, however, it is regrettable that apparently no chance of a blood or fluid examination for syphilis occurred, especially since in some cases of what has appeared to be heat-stroke a syphilitic basis has been present. Experimental investigation has shown that the effect of extremes of heat on the organism is to produce a state of coagulation-necrosis of nerve cells. Pathological changes consisting in meningeal congestion, minute hæmorrhages in the white matter, coagulation-necrosis of nerve cells, with chromatolysis of the Nissl substance and swelling and disintegration of cell nuclei, have been described in recent cases of heat apoplexy. The possible localisation of the symptoms in Dr. Stewart's interesting case is a matter of some difficulty. He concludes that some of the symptoms were clearly due to implication of the cerebrum, notably the epileptiform attacks, the spastic paralysis, the speech disturbances, the emotional condition, and "weakmindedness." The residual symptoms, which chiefly characterised the patient's clinical state when he came under observation, are attributable, according to Dr. Stewart, to organic disease of the cerebellum. It might be suggested that much of the clinical syndrome appears due to involvement of areas in the supply of the basilar artery and its branches. A case reported (in a shorthand journal) by the late Sir William Gowers, of occlusion of the basilar from an endocarditic embolus bears a close resemblance, as far as the involvement of ponto-cerebellar and ponto-medullary mechanisms are concerned, to Dr. Stewart's case. In it, further, there was an initial body temperature of no less than 110° F., carefully verified by more than one thermometer, though, of course, heat apoplexy was out of the question. Evidently, however, in the case of the soldier the condition was widespread in its beginning. Of its organic nature there is no question. The occurrence of such organic nervous changes in association with heat-stroke is worthy of note. Dr. Stewart has reported a case of considerable clinical importance and of much interest.

ETHER DAY IN LONDON, OCTOBER 16.

IT was a happy thought on the part of the old house physicians and surgeons of the Massachusetts General Hospital, attached to various American base hospitals in England, to celebrate the introduction of surgical anæsthesia. Ten years ago the trustees of the Massachusetts General Hospital decided to set apart Oct. 16th as "Ether Day" in commemoration of the first public demonstration and the practical introduction of anæsthesia in surgery. The occasion is worthy to be held in everlasting remembrance. John Collins Warren (the second of the name of the distinguished family, five generations of which have adorned the profession of Boston) performed the operation and realised the extraordinary importance of a discovery that would awaken, as he predicted, the gratitude of the present and of all coming generations. To keep alive the memory of the occasion is the object of Ether Day, and already important addresses have been given by Professor Welch, President Eliot, and others in commemoration of the event. About 20 Massachusetts Hospital men assembled at dinner recently under the chairmanship of Colonel Washburn, the superintendent of the hospital, and now in charge of American hospitals in England. General Winters and Sir William Osler were the only guests. The latter told the story of the introduction of surgical anæsthesia, and showed what an old practice it was and how, time out of mind, patients had been rendered insensible by potions or vapours, without any one man forcing any one method into general acceptance, or influencing in any way surgical practice. Before Oct. 16th, 1846, surgical anæsthesia did not exist; within a few months it had become a world-wide procedure. The original papers of Bigelow and Warren, and those of William T. G. Morton (to whom the full credit for the introduction was given) were exhibited.

PHLEBITIS DUE TO EFFORT

APART from traumatic subcutaneous rupture of veins thrombo-phlebitis is generally regarded as due to infection. However, cases have been recorded in the upper limbs, principally on the right side, which were apparently spontaneous in origin, there being no source of infection. Such cases have been described, sometimes improperly, as phlebitis due to effort. In the *Progrès Médical* M. Jean Murard has reported the following case:—

An artilleryman, aged 24 years, was admitted to hospital for a swelling of the right upper limb. A fortnight previously he had to do some urgent work on his battery which necessitated great efforts of the right arm for two days and nights, with only short intervals of rest. After this he had a sensation of great fatigue in the whole upper limb and noticed small varices in the upper third of the arm. On the following days the sensation increased and the limb felt heavy. Two days before admission he noticed œdema of the arm, which extended to the forearm and then to the hand. A medical man ordered hot fomentations and painting with tincture of iodine. As there was no improvement he diagnosed phlegmon and sent the patient to hospital for incision. On examination the limb was œdematous from the deltoid region to the fingers. The œdema was greatest in the region of the elbow. The whole circumference of the upper third of the arm showed a series of varices. On palpation the œdema was hard and did not take the impression of the finger. In the line of the great vessels there was a tender spot. The general condition was good, the temperature was normal, and minute examination

of the viscera, particularly of the heart, was negative. The limb was put up in a splint. Eleven days later the varices had disappeared in an œdema which was a little more marked. Six weeks later the œdema was slightly less, but six days after this it was in the same condition and the patient had to be evacuated.

In several of the published cases of phlebitis due to effort the influence of the latter is doubtful. Here it was undoubtedly the cause. M. Murard adopts the theory of Lenormant that fatigue leads to muscular contractions which are less regular and harmonious and produce dragging and small ruptures of collateral veins at the point of entrance into the main vein, at which points the thrombosis originates. Phlebitis due to effort would thus be a variety of traumatic phlebitis.

STANDARDISATION OF PATHOLOGICAL METHODS.

IN an original article in our present issue Dr. W. d'Este Emery deals at length with the important matter of the standardisation of the Wassermann reaction, suggesting that, whatever the technique employed, the results should be reported in terms of Wassermann units. The value to the clinician of reports in such a form can hardly be exaggerated. A further substantial contribution by the Medical Research Committee to the present-day needs of pathologists and through them to clinical medicine, appears in the series of Special Reports (No. 19), which contains two memoranda of the Committee upon the Standardisation of Pathological Methods. The first of these deals with the laboratory diagnosis of gonococcal infections, in which the assistance of Lieutenant-Colonel L. W. Harrison, R.A.M.C., has been available. After enumeration of the localities to be examined for the presence of gonococci, methods are recommended for their microscopic identification and cultivation. Jensen's modification is preferred to the original Gram's method, and an excellent coloured plate is given of the appearances of gonococcal pus thus stained. For the cultivation of the gonococcus three media have been found eminently satisfactory in a series of comparative tests made by Captain David Thomson, R.A.M.C., at the Military Hospital, Rochester-row, London. These are (1) Thomson's human plasma-glucose agar; (2) Cole's tryptic blood agar; and (3) Gordon and Hine's trypsinised pea-extract agar. Full details of preparation are given in an appendix. Caution is enjoined in regard to the production of a focal reaction by the employment of a gonococcus vaccine or by the introduction into the urethra of a solution of silver nitrate for diagnostic purposes. Much space is given to a full consideration of the complement fixation test. Four methods have been selected, and they are described in the actual language of their originators. The first, taken from the *American Journal of Medical Sciences*, is the method of Schwartz and Meheil; the second, quoted from the *Journal of the Canadian Medical Association*, is the method of Major J. J. Ower, C.A.M.C.; the third is Kolmer's method, and is abstracted from Dr. Kolmer's "Practical Text-book of Infection, Immunity, and Specific Therapy"; the fourth method is communicated to the committee by Captain Thomson, who carried out the work at the Military Hospital, Rochester-row, under Colonel Harrison. This test promises well as an aid to the diagnosis of gonococcal infections, and the committee have acted wisely in bringing together within one cover the methods employed by those who have most closely studied the subject. The second report deals with methods for the detection of spirochætes. The subject is a more familiar one, and perhaps on this account less attention has been paid to clarity in choice of language and illustration. Dark-ground illumination is described, as well as the methods for staining spirochætes or rendering them visible by the Indian-ink, Congo-red, and silver-nitrate methods. The two reports will fill a gap in the working bookshelf of laboratory investigation of venereal disease.

SANITARY INSTRUCTION IN CHICAGO.

THAT our American Allies are fully alive to the importance of sanitary instruction as a means of safeguarding the people's health is proved in the case of Chicago, the health department of which city issues weekly a bulletin showing the mortality from several important diseases in a population exceeding 2½ millions. The data in the present bulletin refer to the several months of the current year up to and including August. The bulletin sets forth the remarkable fall in mortality in the first eight months of this year in contrast with that of the corresponding period of 1917. The life saving is represented by a total of 3835 persons. Dr. John Dill Robertson, the Commissioner, presents a table showing the deaths from pneumonia and from what he terms the chief degenerative diseases—viz., cancer, diabetes, cerebral hæmorrhage, organic heart disease, cirrhosis of the liver, and chronic nephritis. He also gives the relative "morbidity" from the principal diseases. In the eight months of the present year there were 1167 fewer deaths from pneumonia, representing a reduction of 31·2 per cent., as compared with the mortality from this cause in the corresponding period of last year. Although the rates now given are not strictly comparable with the rates of a full 12-month period, they are instructive as showing the remarkable reduction in mortality recently achieved. The degenerative diseases taken together caused 297 fewer deaths in the eight months under notice as compared with the same period of last year. Indeed, all the diseases of this category showed decrease, with the single exception of cancer, which, in Chicago as elsewhere, is regarded as the *bête noire* among diseases, being less amenable than other conditions to sanitary control, in spite of the intensive study now devoted to its nature and causation. Dr. Robertson draws attention to the necessity of early resort to surgery as the one hopeful means of arresting the condition when once its existence has been ascertained. If the war goes on it is inevitable that America will have to face enormous losses among her soldiers; and as these losses can only be made good from the ranks of the children now being reared, it is imperative that measures should be taken to save the infant lives which are now being needlessly sacrificed. The Chicago weekly bulletin does good service by pointing out these ancient truths to the public. When the public knows that many thousands of infants who now die might be saved by certain well-known preventive methods, and that much of the waste of infant life occurs in the early days after birth, because of the lack of suitable care of the mother before and during confinement, it is certain that well-devised efforts to remedy such scandals will be witnessed. It is the duty of the constituted authorities to convince the public of the necessity of saving young life by pre-natal and obstetrical care for the mother, and the bulletins of the Chicago health department are excellently drawn up for this purpose.

DISPENSARY SUPERVISION IN PULMONARY TUBERCULOSIS.

BY GEORGE JESSEL, M.A., M.D. OXON., D.P.H.,
TUBERCULOSIS OFFICER TO THE LANCASHIRE COUNTY COUNCIL; TUBERCULOSIS OFFICER, WIGAN; AND MEDICAL ADVISOR, WIGAN INSURANCE COMMITTEE.

THE interim report of the Departmental Committee on Tuberculosis contains the following passage:—

"It should, however, be borne in mind that a short stay in an institution in which the patient may be educated, followed by a course of home treatment in shelters, &c., under close supervision is a form of sanatorium treatment which has certain advantages and which may be successfully adopted in a large number of cases."

Home treatment was, of course, prior to this report the principal if not the only form of treatment in the great majority of cases, but the element of close supervision was probably rarely exercised except as regards the middle and upper clases; furthermore, there is reason to believe that the precise manner in which this supervision should be exercised was not generally understood, even in cases where the family doctor was able to enforce a discipline which is admittedly irksome to many patients.

The aim of this paper is to indicate in some degree the value, both to patient and doctor, of systematic dispensary supervision as exercised from Wigan, over an area of about 40 square miles, for over five years.

Criticisms of Home Treatment.

There are still some who condemn home treatment as dangerous and impossible, and figures are from time to time brought forward which are intended to prove this conclusion. Thus, Dr. O. M. Holden has recorded a series of 1956 patients, of whom 794 gave a definite history of tuberculosis occurring amongst 1081 intimate members,[1] and more recently[2] he has published additional figures, the purport of which is to show that home treatment is a menace to the other inmates of the house. Holden's figures, however, as they stand by no means make out a case against home treatment. Alleged secondary cases occurred in about two-fifths of his first series, and the alleged secondary infection affected only 1¼ of a family out of the average 4¼. In addition, Holden apparently ignores all the other factors—viz., second cases occurring from the same source as the original case, or from quite other sources as the result of insufficient or improper feeding, insanitary homes, overwork, intemperance, individual susceptibility, &c. Furthermore, the total number of individuals (suffering and non-suffering) in the families concerned is omitted.

Holden's figures are thus inconclusive and of little scientific value. Even if they could stand the test of close examination, it would still be necessary to show that in the families concerned that element of close supervision, without which home treatment is admittedly often useless and dangerous, was present. In the experience of the writer secondary cases in the same home are by no means common where supervision is exercised in the home. This, indeed, is what would be expected in the light of modern knowledge. Apart from individual cases of unusual susceptibility, massive infection and lowered resistance are the principal factors in the causation of secondary cases of tuberculosis. Dispensary supervision, if properly applied, will usually effectively counteract these elements.

Home Treatment in Wigan.

Although no case has been made out against home treatment on the ground of danger, the question may fairly be asked whether there is any proof that patients suffering from phthisis can have their immediate surroundings and way of living brought into any reasonable degree of accord with sanatorium practice, this being of course, the aim of home treatment. Sir William Osler has tersely summed up the essentials of treatment as "education, control, and a rigid regimen," and it is essentially in these directions that the efforts of the general practitioner can be assisted at, and in connexion with, the dispensaries.

The problem of sleeping accommodation is often a very difficult one, and it is usual to find the patient in bed in the kitchen at the first visit of the dispensary staff after a case has been notified. Similarly, patients are found to be very careless with their sputum. It is necessary to conclude either that clear and definite instructions on these and kindred topics have not been given by the medical attendant or that, if given, they have not been enforced. The improvements that were effected by three of the dispensary nurses of the Lancashire County Council in 1915 with regard to 361 new cases have already been published.[3] They may be summarised as follows:—

Results obtained by Three Dispensary Nurses in 1915.

—	(A)	(B)	(C)	Total.
On nurse's first visit	157 = 43·49%	57 = 15·78%	147 = 40·72%	361 cases.
,, last ,,	262 = 72·57%	53 = 14·68%	46 = 12·74%	

Results obtained by Four Dispensary Nurses in 1916 and 1917.

Results in 1916 ..	799 = 68·8%	186 = 15·9%	179 = 15·3%	1164
,, 1917 ...	1150 = 70·26%	286 = 17·7%	179 = 11·08%	1615

(A) Separate bedroom—i.e., complete isolation. (B) Separate bed, not separate bedroom—i.e., partial isolation. (C) Not satisfactorily isolated.

That this was no spasmodic effort is shown by the results obtained by four dispensary nurses in the Wigan area during 1916 and 1917. Thus in 1917 complete isolation was obtained in over 70 per cent. of 1615 cases of phthisis occurring in an average industrial area of Lancashire, while partial isolation was obtained in an additional 18 per cent. It is clear that the dispensary nurses have accomplished a great work as the result of tact and perseverance. Home treatment is thus possible and safe in about 70 per cent. of cases occurring in the industrial areas of Lancashire at any rate, and the remaining 11 to 15 per cent., which were not satisfactorily isolated, is a measure of the need for isolation and treatment in hospitals as distinct from sanatoriums.

The Exercise of Dispensary Supervision.

Dispensary supervision is largely exercised through the frequent regular and periodic visits of the nurses to patients' homes. These visits vary in frequency according to the urgency of the need, but cases with active disease are visited without notice at least once a month, and sometimes much more frequently. During 1916 the five dispensary nurses paid 12,308 visits to 2306 cases of tuberculosis (all forms, many quiescent or arrested), and during 1917 13,179 visits to 2722 cases.

This, however, is by no means the only way in which dispensary supervision is exercised. All cases with active disease are examined by me as tuberculosis (consulting) officer once in two to three months, either at home or at the dispensary. When visits are paid to the home it is possible to see that the supervision is being properly exercised and that the advice and instructions given are being carried out. The dispensary nurses report upon each case after every visit, and any difficulties that may be met with can then be conveniently discussed. Patients who are not working and who are fit and able to attend the dispensaries are encouraged to do so every fortnight to get weighed, and to have their temperature records checked.

The supervision is not confined to preventive measures, but also concerned with regard to treatment. Thus, in addition to the provision of paper handkerchiefs and bags for sputum, thermometers and record cards are provided for suitable patients, and the large number of properly kept temperature records is remarkable.

Dispensary supervision is not only exercised by means of direct access to the patients. There is close association with the general practitioners, and every effort is made to work in close accord with them. They receive intimation of place and time of each medical examination, and some regularly attend in consultation in spite of the strain of existing war-time circumstances; otherwise, a letter is sent whenever there is anything to communicate on either side.

In addition to the above, the six care committees are of the greatest value, as has been elsewhere described,[4] in rendering home treatment possible by the provision of nourishments, clothing, bedsteads, bedding, &c., and many of the cases are visited by a member of the committee. Patients thus have additional encouragement and inducement to carry out their treatment properly. There is a growing list of patients receiving dispensary supervision only—i.e., patients whose disease is arrested or quiescent. These are kept under surveillance by occasional visits or communications.

Elements of Success.

It is clear that the success of dispensary supervision depends upon the close attention to detail that is given with regard to each individual case. Every patient needs special consideration and must be studied in relation to his environment. Dr. Pratt, of Boston, U.S.A., has achieved no little success by means of close supervision exercised in connexion with his "tuberculosis class." Thus, during the years 1906 to 1913, 165 patients were discharged, 35 of whom had tubercle bacilli in their sputum at some stage of the illness. In 1915, 58·2 per cent. were well and working, free from all symptoms of disease. Of the 35 cases in which tubercle bacilli were found, in 1915 74·3 per cent. were well and working.

In the experience of the writer, efficient dispensary supervision has resulted in a considerable measure of success in spite of the fact that a large proportion of the cases come under notice when already in an advanced stage of disease. There is every reason to believe that with earlier diagnosis and notification, home treatment under close supervision, such as apparently can usually only be obtained through the dispensary organisation, will fully justify on a large scale the conclusions of the Departmental Committee.

THE UTILISATION OF VACCINE FOR THE PREVENTION AND TREATMENT OF INFLUENZA.

AT a Conference on preventive vaccination for influenza held at the War Office on Oct. 14th the following were present: Colonel Sir William Leishman, K.C.M.G., C.B., F.R.S., K.H.P., in the chair; Deputy Surgeon-General P. W. Bassett-Smith, C.B., C.M.G., R.N.; Lieutenant-Colonel D. Harvey, C.M.G., R.A.M.C., officer in charge, Vaccine Department, Royal Army Medical College; Major F. W. Andrewes, F.R.S., R.A.M.C. (T.), pathologist, St. Bartholomew's Hospital; Captain S. R. Douglas, late I.M.S., Inoculation Department, St. Mary's Hospital; Dr. J. W. H. Eyre, Director of the Bacteriological Department, Guy's Hospital. Professor W. Bulloch, F.R.S., pathologist, the London Hospital, was unable to attend.

The Director-General, after welcoming the members, explained to them the object with which they had been called together, and the great and urgent importance of their endeavouring to formulate definite recommendations as to the employment of vaccines, in view of the probability of an extension of the epidemic of influenza.

The committee then proceeded to discuss the items of the agenda form, which had been drawn up by the chairman, and reached the following conclusions:—

1. After discussing the available evidence as to the bacteriology of the present epidemic, the majority of those present were agreed that there was considerable doubt as to the primary etiological significance of the *Bacillus influenzæ* of Pfeiffer, and considered that the existence of some as yet undiscovered virus must be regarded as possible. They had, however, no doubts as to the very frequent presence of Pfeiffer's organism in this epidemic, nor as to the great importance of the part which it played in the production of the symptoms and complications of the disease. The organisms most frequently associated with the *B. influenzæ*, and in their opinion, chiefly responsible for the gravity of the secondary pulmonary complications, are pneumococci and streptococci.

2. The general question of the employment of a bacterial vaccine for the control of the incidence and severity of the epidemic was discussed, and it was unanimously agreed that inoculations with a suitable vaccine might be expected to be of value in both directions.

3. The appropriate constitution of such a vaccine was then thoroughly discussed in the light both of the personal experience of the members of the Conference and of the information available from medical literature. It was agreed that the three following organisms only should be employed, the *Bacillus influenzæ*, the pneumococcus, and the streptococcus. In each instance it was decided that a number of different strains and types of each organism should be utilised in the preparation of the vaccine, and that these strains should have been recently isolated from cases occurring during the present epidemic and should be submitted to strict tests as to race and type prior to use.

4. The relative proportions of the different organisms and the dosage of the vaccine were then dealt with, and it was agreed that the following should be its constitution and dosage:—

	1st dose.	2nd dose.
B. influenzæ	30 millions.	..... 60 millions.
Pneumococcus ...	100 ,,	..... 200 ,,
Streptococcus	40 ,,	..... 80 ,,

The vaccine should be sterilised by a temperature of 55° C., maintained for half an hour, and 0·5 per cent. of carbolic acid should subsequently be added as an antiseptic.

5. Whenever possible, both doses of the vaccine should be given at an interval of 10 days. It was thought that the reactions to be expected from this vaccine would, in the majority of cases, be either trivial or non-existent. It was, however, considered to be of great importance that, in the case of soldiers, a period of 24–36 hours' light duty should always be given.

6. As regards the conditions under which this prophylactic vaccine should be employed, the Conference were unanimous in considering that, whilst it would be preferable to carry out the inoculations before exposure to infection, there do not exist any adequate grounds for withholding it in the case of a body of men amongst whom influenza had already appeared, provided that care was taken not to inoculate any individuals who have fever or are obviously ill, or those who are at the time suffering from catarrh. At the same time, a careful watch should be kept for any evidence of a period of increased susceptibility following upon inoculation, and should this become manifest it is advised that instructions be given to lower the doses recommended above.

7. The Conference made the following recommendations as to dosage of the vaccine in the special cases mentioned below:—

(*a*) *Children.*—It is not advisable to inoculate children under the age of 3. For older children the following doses may be given:—

From 3–7 years	...	¼ of the full dose, as detailed in para. 4.
,, 7–16 ,,	...	½ ,, ,, ,,
Above 16 ,,	...	the full dose ,, ,,

(*b*) *Colonial Troops.*—In this case they recommend three doses at intervals of 10 days, as follows:—

1st dose	...	½ of the "first dose," as detailed in para. 4.
2nd ,,	...	the "first dose," ,, ,,
3rd ,,	...	the "second dose," ,, ,,

(*c*) *Native Contingents.*—Here, too, they recommend three doses at intervals of 10 days, as follows:—

1st dose	...	the "first dose," as detailed in para. 4.
2nd ,,	...	the "second dose," ,, ,,
3rd ,,	...	the "second dose," ,, ,,

8. The Conference then discussed at length the question of employing the vaccine for the treatment of severe cases of influenza and its complications. On this they make the following recommendations:—

(*a*) The vaccine is most likely to be of service in the treatment of subacute and of chronic cases; in this class of case the initial dose which they recommend is 1/5 of the "first dose," as detailed in para. 4.

(*b*) The use of the vaccine in the treatment of severe cases of secondary broncho-pneumonia cannot at present be recommended, in view of the dangerous rapidity and severity of many of these cases. Should it, however, be desired to try the vaccine in such cases it is advised that the initial dose should not exceed 1/20 of the "first dose," as detailed in para. 4.

9. A profitable discussion then followed upon technical details and upon the investigations bearing upon the subject which were felt to be desirable and likely to lead to practical improvements in respect of the employment of vaccine. These hardly admit of summary, but it was agreed that among the most important were the questions of the unity or multiplicity of types of the *B. influenzæ* and of the identification of this organism, and some arrangements were made between the members for exchange and collection of cultures, which it was hoped would lead to progress in these directions.

10. The committee then considered the practical steps to be taken for the preparation of the vaccine on the assumption that considerable demands might be made for it at an

early date. Thanks to the generous assistance offered by the members of the Conference, this was placed upon a satisfactory basis, it being agreed that the numerous strains of the organisms which were in possession of most of the members, and which had been obtained from recent cases, should be sent to Captain Douglas, at St. Mary's Hospital, where he has kindly consented to put them through the necessary tests as to purity, type, &c. Those selected will then be passed on to Lieutenant-Colonel Harvey at the R.A.M. College, who will arrange for the preparation of the vaccine for Army purposes, and also to Deputy Surgeon-General Bassett-Smith at the Royal Naval College.

11. In order to ascertain the degree of protection given by the vaccine the Conference recommend strongly that the necessary administrative steps be taken to secure statistical records dealing with the following matters:—

(*a*) The reactions following the inoculations.
(*b*) The occurrence of any cases of severe illness within 48 hours of inoculation.
(*c*) The incidence of the disease among the inoculated and uninoculated.
(*d*) The incidence of complications among the inoculated and uninoculated.

CONFERENCE OF THE BRITISH HOSPITALS ASSOCIATION.

The Voluntary System and the Ministry of Health.

A CONFERENCE of members of this association was held on Oct. 18th at St. Thomas's Hospital under the chairmanship of Mr. H. WADE DEACON, of the Liverpool Royal Infirmary. There was a good attendance, and those present included Sir Arthur Stanley, M.P., Sir George Makins (representing the Ministry of Health Committee of the Royal Colleges of Physicians and Surgeons), Sir Henry Burdett, and the Rev. G. P. Cronshaw.

Sir GEORGE MAKINS proposed the following resolution:—

That the British Hospitals Association welcomes the proposal to form a Ministry of Health. The Association is strongly of opinion that the interests of the patients and of the community as a whole, the progressive education and training of doctors and nurses, and the prosecution and advance of scientific research, will be best served and provided for in the scheme by the retention of the voluntary hospital system.

He said the proposal to form such a Ministry was meeting with the support of the nation and the medical profession alike. The interest of this meeting was mainly in the future of the voluntary hospital system, a system that was one of the links with the past of which the nation had most reason to be proud. In this country the voluntary hospitals had been the home of medical training, and had exerted a great influence in making the general practitioner a highly skilled man. It had been said that a central administration of medical schools would tend to uniformity and increased efficiency. But while something might be said for that view, it would tend to reduce every institution to the same level, possibly a dead level, and they would be cramped and hampered by official administration; and such a change would remove the spirit of emulation between schools and between hospitals which had done so much to advance medical teaching and treatment. During a long life as teacher and examiner he had always felt he gained much knowledge and experience from having come into contact with students from various schools. And a side which he feared would be lost if all hospitals were to be massed under one central administration was the social side, and especially the fine work of the hospital almoner, whose efforts were directed to the patient's welfare after his or her departure from the hospital to insure the best results from the treatment which had been received. The hospitals had done a great work in connexion with maternity and infant welfare and in getting the treatment of tuberculous patients put upon a proper basis. That was largely because these hospitals were individual institutions, free to undertake any enterprise which seemed to promise well; this was less likely to be done by a central administration. Voluntary hospitals owed much of their success to the very strong sympathy which existed between the general public and the charitable aims of the hospitals. He thought the expression "charitable work" ought to be interpreted in the religious sense—not so much a matter of receiving money as one of doing good to others. This feeling of sympathy was the channel along which sentiment was developed into action, and sentiment was, after all, responsible for many of the greatest things which had ever been accomplished.

The Rev. G. P. CRONSHAW seconded the resolution. He said the voluntary hospital principle in this country was the envy of the whole world. America was now trying to get back to it after a trial of the State administration of hospitals; and Australia and New Zealand were coming to the same conclusion. Our hospitals had now to set their houses in order, for they would be required to do something more than in times past. The middle classes were asking very pertinently why only the poorest in the land should have the advantage of specialist knowledge, skill, and equipment. Middle-class people could not afford to pay a specialist, but they could contribute something. The Association would welcome a Ministry of Health, because it would obviate dealing with a variety of different departments according to the subjects concerned. He welcomed also a system by which every doctor would be able to follow his own patients into the hospital. Hospitals could accept money from public funds without losing their voluntary character. In the matter of National Insurance the voluntary hospitals had stood between the nation and the complete collapse of the Act. He looked for the time when nurses engaged on special work could periodically re-enter their hospital for the purpose of keeping themselves up to date.

Sir HENRY BURDETT warmly supported the resolution, and advocated the Association applying for a Royal Charter. There would have to be payment of what were now the honorary staffs of hospitals, especially if the hospitals catered for all classes of the community. He spoke highly of the work of the almoners' department, and thought every hospital should have a medical superintendent, who should, however, have no concern with the finances. In America such an individual received more than he was likely to earn by the exercise of his profession outside, and such posts were very carefully filled.

A number of suggestions were made by various speakers. These included a more extensive hospital propaganda, more working-class representation on hospital boards, the coöperation of large hospital funds, the establishment of pay wards at moderate fees, the organisation of parties of hospital visitors, the throwing of the voluntary hospitals on the mercy of the Charity Commissioners to preserve their character as against the Poor-law institutions which would be taken over by the new Ministry, and the bringing of all hospitals up to a high standard, so that the authorities would be very unwilling to alter them.

Sir ARTHUR STANLEY considered that the meeting was thoroughly agreed that a Ministry of Health would come and that the voluntary hospitals had got to remain. They had nothing to fear from the new Ministry, and Dr. Addison had told him in conversation that those in charge of the Bill had no intention of trying to enforce any particular principle or doctrine of their own. The voluntary hospitals needed a good advocate, and he suggested the formation of a Parliamentary Committee to watch the Bill, for the Association could now claim to represent practically all the voluntary hospitals of the country. He agreed that a Royal Charter, if well and clearly drawn, would be a good weapon for the Association to possess. He made these recommendations with the more freedom as he did not intend to be in the next Parliament.

The resolution was unanimously accepted.

The following further resolution was also passed:—

That the Council be requested, when the terms of the Ministry of Health Bill are known, further to consider the question with reference to its provisions; to take such steps as, at their discretion, they may determine; and report.

The meeting concluded with votes of thanks to the governors of St. Thomas's Hospital for the use of the room, and to the chairman for presiding.

LONDON ASSOCIATION OF MEDICAL WOMEN.—A meeting was held at the Medical Society of London on Oct. 8th, Lady Barrett, the President, being in the chair. The annual report was read, and the new constitution and rules read and approved. Dr. Constance Long read a paper on "The Significance of Phantasy in the Production of the Psycho-neuroses." A discussion then followed, in which Dr. Helen Boyle, Dr. Jessie Murray, Dr. Mary Bell, and Lady Barrett joined.

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

A MEETING of the Executive Committee of this Fund was held at the offices of THE LANCET on Monday, Oct. 21st, Sir RICKMAN GODLEE being in the chair.

The HON. SECRETARY reported that the 12 City Livery Companies had been approached with a request for financial help. No answers had been received from four of the Companies, and in the case of the remainder the reply amounted to a qualified refusal in all except one.

The munificent gift of £200 monthly from the American Red Cross was gratefully acknowledged by the Committee. Mr. Ernest P. Bicknell, Commissioner for Belgium of the American Red Cross, wrote to the chairman in August last announcing this intention, and asking to be kept informed of the progress of the Fund. A statement of the activities of the Fund and its existing position having been sent to him by the Hon. Secretary, a letter was received from the American Red Cross confirming the subsidy of £200 per month to the Fund until the end of the year, and alluding to a possibility of its continuance for a longer period. The Committee, while acknowledging with gratitude this magnificent gift, felt certain that the British medical and pharmaceutical professions would continue to contribute their share to the Fund.

In regard to the new situation created by the Allied advance, Sir RICKMAN GODLEE understood that local Belgian Committees would continue to act in the regained territory, although doubtless the need would not be so urgent as in the parts of Belgium still occupied.

The HON. TREASURER presented an audited cash statement from Dec. 1st, 1917, to August 31st, 1918, showing that £3924 0*s.* 3*d.* had been expended in relief and £161 0*s.* 7*d.* in administration, including the cost of the recent Special Appeal, leaving a balance in hand of £1289 17*s.* 1*d.* He added that the first part of the Second Appeal in the New Year had brought in about £963; the circular letter to the medical profession then produced a further £1715; and a special article in the medical press £1455; a total of about £4134—a sum exceeding the auditors' statement, inasmuch as £286 had been subscribed since Sept. 1st. The monthly payments, which began in May, were bringing in £16 3*s.* 6*d.* per month.

It was decided to continue to send to Belgium a mensuality of £400 a month until the end of the year.

URBAN VITAL STATISTICS.

(Week ended Oct. 19th, 1918.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality was 20·7, against 12·6 and 15·1 per 1000 in the two preceding weeks. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 20·1, or 6·2 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 5·4 in West Bromwich, 6·0 in Smethwick, and 6·4 in Rotherham, to 46·0 in Birkenhead, 46·2 in Liverpool, 48·3 in Gloucester, 58·3 in Southampton, and 68·6 in Portsmouth. The principal epidemic diseases caused 212 deaths, which corresponded to an annual rate of 0·7 per 1000, and included 89 from infantile diarrhœa, 61 from diphtheria, 20 from whooping-cough, 16 from measles, 15 from scarlet fever, and 11 from enteric fever. The deaths from influenza numbered 1895 and included 371 in London, 215 in Liverpool, 178 in Portsmouth, 81 in Southampton, 71 in Hull, 69 in Sheffield, and 62 in Cardiff. The 1241 cases of scarlet fever and 1205 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 93 and 23 above the respective numbers remaining at the end of the previous week. The causes of 55 deaths in the 96 towns were uncertified, and included 21 in Liverpool, 5 in Birmingham, and 3 each in Portsmouth, Hull, and South Shields.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,500,000 persons, the annual rate of mortality was 28·3, against rates steadily increasing from 10·6 to 24·7 per 1000 in the five preceding weeks. Of the 1303 deaths from all causes, 63 were classified to influenza, which was also stated as a contributory cause in 426 deaths classified to other diseases; in the previous week these numbers were 45 and 339 respectively. The 820 deaths in Glasgow corresponded to an annual rate of 38·4 per 1000, and included 10 from whooping-cough, 5 each from diphtheria and infantile diarrhœa, and 1 from measles. The 83 deaths in Edinburgh were equal to a rate of 13·0 per 1000, and included 2 from whooping-cough and 1 each from scarlet fever and diphtheria.

Irish Towns.—The 295 deaths in Dublin corresponded to an annual rate of 38·6, or 14·0 per 1000 above the rate recorded in the previous week, and included 8 from infantile diarrhœa, 4 from whooping-cough, and 1 from diphtheria. The 83 deaths in Belfast were equal to a rate of 11·0 per 1000, and included 5 from infantile diarrhœa and 2 each from scarlet fever and diphtheria.

Correspondence.

"Audi alteram partem."

A NEW TYPE OF INFLUENZA.

To the Editor of THE LANCET.

SIR,—Surely we are seeing a type of influenza quite different from anything we have seen before. Side by side with influenza of the ordinary type we are meeting with cases which exhibit the following symptoms and physical signs. Within a few hours of seizure the patient's temperature runs up to 105° or over, while the pulse ranges round 90; a high temperature with a slow pulse; the lips and face exhibit marked cyanosis, and epistaxis frequently occurs. In the course of a day or two the patient begins to spit up a quantity of frothy sputum tinged with bright blood. In spite of the fever the pulse is regular, of good volume, and fairly strong, and the rate is generally below 100, at times below 90. On examination the area of cardiac dullness is not increased, and there is no evidence of distension of the right side of the heart. For the first day or two the physical signs in the lungs are very indefinite and point to capillary bronchitis rather than to a bronchopneumonia; later on there may develop signs of patches of consolidation. During the past six days among a large number of patients I have seen about a dozen cases such as I have described. In two instances I have seen the changes exhibited on the post-mortem table. In both cases the lungs were emphysematous and showed signs of recent pleurisy. Scattered patches of purpura were present. On section patches of capillary bronchitis appeared to surround small patches of consolidated lung, which sank in water; distinct areas of hæmorrhage into the lung tissue were present. I well remember the severe epidemic in 1889–90, and attended a large number of cases, but the signs and symptoms to which I refer, and which have been exhibited by patients I have attended during the past few days, are quite new to me.

Are we dealing with a new organism or with the recognised organisms of influenza which have for some reason attained greater virulence?—I am, Sir, yours faithfully,

Oxford, Oct. 23rd, 1918. WM. COLLIER.

NASO-PHARYNGEAL INFECTION AT THE ONSET OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—I do not intend to be drawn into a long correspondence upon side issues. If, however, you think that the scientific basis of the discussion has any general interest I will re-state my case shortly and, I hope, clearly as follows:—

Origin of discussion.—Statement made by Lieutenant-Colonel M. H. Gordon: "Every case of cerebro-spinal fever is ..... an instance of a carrier developing the disease." This was a statement of epidemiological importance. Exactly similar views were also held by two authorities quoted by Surgeon S. L. Baker and myself in No. 17 of the Special Report Series of the Medical Research Committee.

Cause of the discussion.—Observations made by Temporary Surgeon Baker and myself published in THE LANCET of Oct. 20th, 1917. These had the effect of disputing the scientific accuracy of the above statement of Colonel Gordon.

1. Twenty-six cases of cerebro-spinal fever were swabbed before the onset of the disease. All were negative. The number has since mounted to 43.

2. Four hundred and eighty-five proved carriers failed to develop cerebro-spinal fever. The number has since mounted to about 700. These carriers were both chronic and transient.

Beginning of the discussion.—Statement in a letter to THE LANCET by Colonel Gordon that we had misunderstood him. We thought we had not, and therefore did not reply, to avoid a polemic.

Outbreak of polemic.—Letter by Major J. Dorgan to THE LANCET nearly a year later, also disputing Colonel Gordon's statement. In the course of his argument he made, independently, exactly the same points as we did and another point relating to the presence of meningococci in the throat *after* the onset of the disease. On this matter we agree with Colonel Gordon rather than with Major Dorgan, but not for the reasons Colonel Gordon advanced and against which I protested in THE LANCET of Sept. 14th.

I am interested only in seeing the idea established that cerebro-spinal fever develops almost immediately upon the occurrence of a naso-pharyngeal infection. If it does not develop immediately it does not develop at all, and the man either becomes a carrier or recovers from the local infection. This seems to me to be quite a different idea from that expressed by Colonel Gordon. He, recognising that the coccus is nearly always to be found in the throat at or shortly after the onset of the disease, says that this implies that the disease has developed in a carrier, and maintains this view against us by saying that he purposely did not bind himself to the *length of time* during which the case had carried; it might have been a very short time, say 24 hours.

This, however, in our opinion, is a totally abnormal and incorrect use of the word "carrier." You do not call a man an "anthrax carrier" during the interval between infection and the appearance of the first signs, nor a man a "pallida carrier" during the incubation period of the disease. Neither can you call a man a "meningococcus carrier" between the time of acquisition of the coccus and the onset of meningitis. If you do, it appears to us to be a confused concept or a quibble. At any rate, it is liable to lead to justifiable misconception.

I am, Sir, yours faithfully,

P. FILDES,
Staff Surgeon, R.N.V.R.

R.N. Hospital, Haslar, Sept. 22nd, 1918.

MEDICAL MEN IN PARLIAMENT: CAPTAIN DONALD CAMPBELL'S CANDIDATURE.

To the Editor of THE LANCET.

SIR,—I have been officially adopted as prospective Parliamentary candidate for North Paddington at the next General Election by the Paddington Branch of the National Federation of Discharged and Demobilised Sailors and Soldiers.

I would like to appeal to my medical brethren for funds to enable me to carry out my political campaign fully and bring the whole to a successful issue. I would respectfully suggest that if a thousand medical men contributed 5*s*. each (as a single, limited, and non-recurring subscription) it would produce £250. Of course, this will be nothing near what it will cost me, but, on the other hand, it will help towards my election expenses, and at the same time be a source of moral comfort during the strain of the elections.

I have done a good deal of spade-work in my constituency, and have a large and weighty following (outside the profession), and with my political experience I am convinced that anyone contesting North Paddington purely as a "medical candidate" would not have the slightest chance of election, and further, in my opinion, of even being reimbursed his £150.

I am willing to speak before any medical gathering, and if the profession hope and intend that some of their members go towards the constitution of the next House of Commons I submit something concrete should be done immediately. Failing this, it just means that those of us who get elected to the House purely as politicians, without the blessing and support of our professional confrères, go to the House qua politicians, and the medical profession still remains unrepresented in the sense desired by a large number of the faculty. We want unity; let us show that we do. I am willing to do my share and more than my share.

I am, Sir, yours faithfully,

DONALD CAMPBELL,
Captain, late R.A.M.C.

70, Sutherland-avenue, Paddington, W. 9, Oct. 18th, 1918.

THE PAY OF TEMPORARY R.A.M.C. OFFICERS.

To the Editor of THE LANCET.

SIR,—I notice a fresh appeal is to be made for medical men both in Ireland and England. Those who come up now will, as in no other branch of the service, receive the same pay as those who have borne the heat and burden of the day. The R.A.M.C. is practically the only corps wherein a man has no expectation of increased pay after three or four years' active service. Is it too late to suggest that the only increase in pay since 1914—viz., children's allowances—should no longer be cut in two because of the fact that we are on consolidated pay instead of pay and allowances?

I am, Sir, yours faithfully,

TEMPORARY CAPTAIN.

Oct. 18th, 1918.

THE SERVICES.

ROYAL NAVAL MEDICAL SERVICE.

To be temporary Surgeon Lieutenants: R. H. O. B. Robinson, E. G. T. Holden, S. C. Woodhouse.

ARMY MEDICAL SERVICE.

Col. J. Meek retires on retired pay.

ROYAL ARMY MEDICAL CORPS.

Capt. (acting Major) J. Patrick, R.A.M.C. (T.F.), to be temporary Lieutenant-Colonel whilst specially employed.

Temp. Lieut.-Col. H. A. T. Fairbank (Captain, R.A.M.C., T.F.) relinquishes his temporary commission on re-posting.

To be temp. Majors: G. E. Waugh, W. P. S. Branson, F. N. G Starr.

Capt. E. G. H. Cowen to be acting Major whilst specially employed.

Temp. Capt. W. V. Robinson relinquishes the temporary rank of Major on re-posting.

Temporary Captains to be acting Majors whilst specially employed: E. McCulloch, A. C. Norman, H. M. Gray, H. E. Gamlen.

The rank of Temp. Capt. C. G. Seligman is as now described.

Temporary Lieutenants to be temporary Captains: J. Menzies, S. G. Trail, A. L. White, E. Reavley, F. S. Adams, J. E. Richards.

To be temporary Captains: A. G. Payne, J. B. Orr, F. W. Twort, W. C. Mayo, P. G. Simpson, W. W. Linnington, H. T. Thomson, H. R. Phillips, P. A. Dykes, P. W. Ashmore, G. R. Lawless, F. H. Cooke, W. H. Weir, Temp. Hon. Capt. D. M. Stone, A. Dingwall-Fordyce, F. P. Grove, E. A. Morgan, H. H. Fairfax.

To be temporary Lieutenants: A. R. Wade, W. Anderson, P. P. Galea, J. A. Martin, E. S. Litteljohn, T. Wallace, C. A. Whitfield, R. Walker, R. L. Wilcox, D. C. Macaskill, F. C. S. Bradbury, R. H. Wace, S. G. Platts, C. W. Branson, W. H. Brooks, R. Tilbury, M. J. Gibson, A. J. Beattie, D. J. Crowley, R. F. Higgin, W. H. Croly, J. E. G. Calverley, G. E. Froggatt, F. Campbell, J. Eadie, A. W. G. Clark, B. G. Reynolds, G. S. Ward, M. Wheeler, G. H. Winch, J. D. Russell, W. F. Waugh, J. Shaw, W. L. Stuart, W. H. Jones, C. P. Lankester, G. Holman, J. D. Walker, J. W. Clyne, J. Dwan, M. D'Albon, A. R. Moore, W. Knapp, J. E. Rea, W. F. Murphy, A. S. L. Biggart, H. W. Hackett, A. J. Hynd, J. Craig, E. Walsh, D. I. McNaughton, R. P. Parker, D. Ferguson, B. F. Howlett.

F. N. Smith to be temporary Honorary Captain.

P. A. E. Sheppard to be temporary Honorary Lieutenant.

R. McL. Gibson to be temporary Honorary Lieutenant whilst serving with No. 11 Stationary Hospital.

H. A. Lownds to be temporary Honorary Lieutenant whilst employed with the British Red Cross Society in France.

Officers relinquishing their commissions: Temp. Major E. C. Stabb (having ceased to be employed at the Manor (County of London) War Hospital); Temp. Capt. (acting Major) H. Dudley (on account of ill-health, and is granted the honorary rank of Captain); Temp. Capts. I. Vandandaigue, R. C. Pitt, A. D. Clinch, W. G. Thomas, A. H. Clough. Temp. Lieut. M. Briscoe.

SPECIAL RESERVE OF OFFICERS.

Lieutenants to be Captains: H. B. Dykes, D. McK. Sutherland, E. N. P. Martland, N. Kietz, R. D. Aylward, W. Eldinow, E. S. Phillips, W. D. Mackinnon, E. J. Coombe, J. Berry, R. F. C. H. Buchanan.

To be Lieutenants: C. C. H. Cuff, J. H. E. Moore and D. A. Dyer (from Leeds University Contingent, O.T.C.), C. D. Hewer (from University of London Contingent, O.T.C.), T. Colley, E. S. Gawne, and F. L. Whincup (from Manchester University Contingent, O.T.C.), B. Sergeant (from Durham University Contingent, O.T.C.).

Hon. Lieut. R. Graham to be Lieutenant.

To be Lieutenants: L. H. Duguid, G. Whittaker, S. H. Kemp.

Major T. W. A. Daman relinquishes his commission on account of ill-health, and is granted the honorary rank of Major.

Major (Brevet Lieut.-Col.) (temp. Lieut.-Col.) C. Rundle relinquishes his temporary rank on ceasing to be specially employed.

Capt. P. W. Edwards relinquishes his commission on account of ill-health, and is granted the honorary rank of Captain.

General List.—Capt. T. Graham, M.C., to be acting Major whilst specially employed. Capt. C. S. Lee relinquishes his commission on account of ill-health contracted on active service, and is granted the honorary rank of Captain.

TERRITORIAL FORCE.

Capt. H. A. T. Fairbank is restored to the establishment on relinquishing his temporary commission in the R.A.M.C.

Capt. (acting Major) J. Patrick is now seconded whilst holding a temporary commission in the R.A.M.C.

Capt. (acting Major) A. C. F. Turner to be acting Lieutenant-Colonel whilst in command of a Medical Unit.

Capts. A. M. Davie and W. Scott to be acting Majors whilst specially employed.

Capt. W. B. Secretan is now seconded for duty overseas.

Capt. (Hon. Col.) Sir Thomas C. English is seconded whilst holding a temporary commission in the R.A.M.C.

Capt. W. G. Paget to be Major.

TERRITORIAL FORCE RESERVE.

Capt. (acting Major) E. B. Hinde, from R.A.M.C., to be Captain.

ROYAL AIR FORCE.

Medical Branch.—Lieut. F. H. Wallace to be Captain. H. A. Hewat (late temporary Surgeon, R.N.) is granted a temporary commission as Captain. T. D. J. Augustine Fuller is granted a temporary commission as Lieutenant. Administrative: Lieut. G. G. Coury, V.C., to be temporary Captain whilst employed as Captain.

THE American Red Cross has given £500,000 to the Joint Committee of the British Red Cross Society and Order of St. John "Our Day" Fund.

THE MEDICO-LEGAL SOCIETY.—A meeting of the society will be held at the rooms of the Medical Society of London, 11, Chandos-street, W., on Thursday, Nov. 14th, at 8.30 P.M., when the President, Dr. F. J. Smith, will deliver an address on Pensions and Their Allotment, to be followed by a debate.

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue :—

Killed.

Lieut. D. G. K. Garrett, R.A.M.C., practised in Canada, and came over with the Expeditionary Force.

Capt. E. L. Jones, R.A.M.C., attached Highland Light Infantry, was a student at Guy's Hospital and qualified in 1913.

Capt. W. S. B. Hay, R.A.M.C., attached R.F.A., qualified at Belfast in 1914. For a short time he practised at Belfast, and joined up early in 1915.

Capt. C. L. Dold, R.A.M.C., attached S. Wales Borderers, qualified at Edinburgh in 1914, and joined up on the outbreak of war.

Capt. J. James, R.A.M.C., attached Highland Light Infantry, was a student at King's College, London, and qualified in 1903. He held appointments at the Westminster Hospital, at the Seamen's Hospital, Greenwich, and at the Western Dispensary, London, and joined the R.A.M.C. in 1908.

Capt. J. M. McLaggan, M.C., R.A.M.C., attached Royal Fusiliers, qualified at Aberdeen in 1913, and joined up on the outbreak of war. The award of the M.C. was recorded in THE LANCET of Nov. 13th, 1915, p. 1112.

Drowned.

Capt. D. Burns, R.A.M.C., qualified in Ireland in 1912, and prior to joining the R.A.M.C., was in practice in Dublin.

Lieut. R. J. Bassett, R.A.M.C., qualified in Ireland in November, 1917, and joined up shortly afterwards.

Capt. R. E. Lee, R.A.M.C., qualified at Dublin in 1910, and held an appointment at the Bootle Borough Hospital. Prior to joining the R.A.M.C. on the outbreak of war he was in practice at Blackrock, Dublin.

Major C. W. Duggan, R.A.M.C., qualified at Edinburgh in 1887, and early chose the Army Medical Service for his professional career.

Capt. M. Murphy, R.A.M.C.

Died of Wounds.

Capt. G. M. Cowper, R.A.M.C., attached Dorset Regiment, was educated at Cambridge and at St. Bartholomew's Hospital, London, and qualified in 1914, and joined up on the outbreak of war.

Capt. W. B. Jack, R.A.M.C., was educated at Glasgow University, and qualified in 1905. He held an appointment at the Glasgow Royal Infirmary, and at the time of joining the R.A.M.C. was in practice at Kendal, Westmorland, where he was honorary medical officer to the County Hospital, police surgeon, and medical officer and public vaccinator to the Grayrigg District of the Kendal Union.

Capt. A. A. Parker, M.C., Canadian A.M.C., qualified at Toronto in 1914, and prior to joining the Expeditionary Force was on the staff of the Hospital for Sick Children at Toronto. The award of the M.C. was recorded in THE LANCET of March 23rd, 1918, p. 450.

Capt. J. W. Frew, R.A.M.C., was a student at Edinburgh University and qualified in 1906. He was in practice for some years at Edinburgh, and afterwards proceeded to Barkly East, South Africa, where he was in practice prior to joining up.

Major S. S. B. Harrison, M.C., R.A.M.C., was a student at Guy's Hospital, London, and qualified in 1914. The award of the M.C. was recorded in THE LANCET of May 19th, 1917, p. 776.

Died.

Capt. G. Finch, R.A.M.C. (T.F.), was a student at St. Thomas's Hospital, London, and qualified in 1905. He held appointments at the Royal Westminster Ophthalmic Hospital, London, and at the Brompton Consumption Hospital, and was at one time school medical officer to the East Sussex County Council. At the time of going on active service he was assistant M.O.H. of East Suffolk. He died at Basra, Mesopotamia, of pleuro-pneumonia.

Lieut. E. H. Glenny, R.A.M.C., was a student at St. Bartholomew's Hospital, London, and qualified in July, 1917, and joined up forthwith. He died of pneumonia.

Capt. G. S. Brock, I.M.S., qualified in Edinburgh in 1910, and before joining the I.M.S. in 1912 he was in practice with his father in Rome.

Col. G. H. Van Zyl, South African Medical Corps, died at Wynberg from pneumonia.

Wounded.

Lieut. W. Hickey, R.A.M.C., attached East Surrey Regt.
Capt. F. B. Day, Canadian A.M.C.
Lieut.-Col. M. R. Taylor, D.S.O., R.A.M.C.
Capt. A. Wilson, R.A.M.C.
Lieut. H. G. D. Mathur, I.M.S.
Capt. A. L. McLean, Australian A.M.C.
Capt. R. F. Matters, Australian A.M.C.
Capt. I. D. Stubbs, R.A.M.C., attached London Regiment.
Lieut.-Col. W. W. Boyce. R.A.M.C.
Capt. W. A. Coats, R.A.M.C.
Capt. W. E. R. Dimond, R.A.M.C.
Capt. S. Hodgson, M.C., R.A.M.C., attached R.G.A.
Capt. M. L. Farmer, R.A.M.C., attached R.F.A.
Capt. G. Moore, R.A.M.C., attached Worces. Regiment.
Lieut. F. L. Richard, R.A.M.C., attd. S. Staffordshire Regt.
Capt. F. N. K. Falls, Canadian A.M.C.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported :—

Major W. Y. Hunter, Canadian Infantry, killed in action, son of the late Dr. W. Hunter, of Margate.

Second Lieut. F. B. Atkinson, R.F.A., killed in action, younger son of Dr. J. A. Atkinson, of Newnham-on-Severn.

Lieut. E. C. Comley, M.C., Royal Munster Fusiliers, accidentally killed, son of the late Dr. J. M. Comley, of Calcutta.

Second Lieut. B. Daunt, Royal Sussex Regiment, killed in action, eldest son of Capt. W. Daunt, R.A.M.C., of Hastings.

Major J. C. L. Young, Alberta Regiment, killed in action, son of Lieut.-Col. J. Young, R.A.M.C., of Alexander-square, London, S.W.

Capt. D. C. B. Cotes, North Staffordshire Regiment, died of wounds, only son of Dr. D. F. B. Cotes, of Burton-on-Trent.

Capt. G. S. Brock, I.M.S., died at Rawul Pindi, India, only son of Dr. G. S. Brock, of Rome.

Lieut. D. R. Campbell, R.N., drowned at sea, younger son of Dr. D. Campbell, of Brixton-hill, London, S.W.

THE HONOURS LIST.

The following awards to medical officers are announced. All are members of the R.A.M.C. except where otherwise stated :—

Distinguished Service Order.

Temp. Capt. WILLIAM GRAHAME COBB, attached K.A.R.—For conspicuous gallantry and devotion to duty in action. For six hours, in the middle of a desperate fight at close quarters, he maintained his dressing station and attended the many wounded. Enemy's fire was coming from three directions, and the only cover was two ant-heaps. He frequently went forward to the firing line and brought in wounded at great personal risk. He undoubtedly saved many lives by his perseverance and determination, all the wounded being safely evacuated under the greatest difficulties.

Temp. Capt. (acting Major) JOHN GREENE, M.C.—For conspicuous gallantry and devotion to duty during an enemy attack. Although his advanced dressing station was heavily shelled and gassed he continued at duty, encouraging all by his courage and resourcefulness. He worked continuously for 30 hours, visiting his bearers' posts under heavy shell fire, and only rested when all wounded had been evacuated. His magnificent devotion to duty saved many lives.

Second Bar to the Military Cross.

Temp. Capt. (acting Major) DANIEL MCKELVEY, M.C.—For conspicuous gallantry and devotion to duty as liaison medical officer. He constantly kept touch with brigade and battalion headquarters, moving over roads and ground exposed to heavy shelling. His tireless energy, organising ability, and disregard of danger were largely instrumental in the successful clearing of casualties from the line.

Bar to the Military Cross.

Capt. VERNON CARLISLE BROWN, M.C., Australian A.M.C.—For great courage and resource in evacuating wounded from a forward area. The routes were being heavily shelled, and he established bearer relay posts in suitable positions after a full reconnaissance of the ground. During the whole operation his perseverance and initiative contributed largely to a quick evacuation of the wounded, while his energy and example stimulated the men.

Temp. Capt. JOHN CHARLES BOILEAU GRANT, M.C.—For conspicuous gallantry and devotion to duty. He attended to wounded men lying in the open under heavy fire, and subsequently for three days and nights, with little rest, he was constantly out with stretcher-bearers searching for and removing the wounded. He was undoubtedly the means of saving many lives, and his fine example was of the greatest value at a very trying time.

Temp. Capt. JOHN NELSON HUMPHREY, M.C.—For conspicuous gallantry and devotion to duty during an enemy attack. As bearer officer he repeatedly led his men up to the front line under very heavy fire. When the normal line of evacuation was broken he carried out a reconnaissance in full view of the enemy, and established a new means of communication, himself assisting to remove a tree across a road which was being heavily shelled. By his courage and resource he contributed largely to the rapid evacuation of the wounded, and saved many lives.

Temp. Capt. CHARLES CLOUSTON IRVINE, M.C.—For conspicuous gallantry and devotion to duty. When the shelter in which he was working received a direct hit from a shell, the explosion of which killed his sergeant and an orderly who were helping him, he was severely shaken but rallied himself and continued to attend to the wounded. A panic which might have ensued among the wounded and shell-shocked soldiers was averted by his courage and determination.

Temp. Capt. WILLIAM GRAEME DENROCHE McCALL, M.C.—For conspicuous gallantry and devotion to duty. When the enemy put down a heavy barrage, causing many casualties in his own and other units, he arranged for the collection of wounded, and attended them with the greatest coolness in the open, which necessitated his remaining in the barrage. Throughout the operations his energy and devotion to duty were admirable.

Capt. (acting Major) CAMPBELL McNEIL McCORMACK, M.C.—For conspicuous gallantry and devotion to duty. During an important engagement he organised the evacuation of the wounded with great skill and devotion to duty, proceeding frequently himself in charge of bearers, through heavy shelling, to the rear aid-posts. It was largely due to his able organisation and fine example of self-sacrificing gallantry that the numerous casualties were evacuated so expeditiously.

Military Cross.

Capt. (acting Major) GALVIN ALEXANDER ELMSLIE ARGO.—For conspicuous gallantry and devotion to duty. While in charge of a light section of a cavalry field ambulance during an attack he performed most useful work. His brigade sustained considerable casualties, and he organised a stretcher party and rescued several wounded, though the ground was being shelled at the time. He showed great coolness and devotion to duty.

Capt. ISAAC MANLY BARROW, Australian A.M.C.—Under heavy fire he dressed wounded in an open trench, and when the battalion attacked he advanced with them and established his dressing station behind the front line. When two of his bearers were wounded carrying a casualty he dashed forward under direct machine-gun fire to their assistance. Later he was severely wounded. Throughout the operations he showed conspicuous gallantry and devotion to duty.

Capt. GEORGE ALBERT BLUMER, Australian A.M.C.—For conspicuous gallantry and devotion to duty. When the R.A.P. was heavily shelled, a direct hit causing casualties amongst the staff, he succeeded, single-handed, in getting the wounded away, and attended to many cases in the area of the bombardment. Throughout the period his courage and devotion saved many lives.

Temp. Capt. STANLEY ARTHUR BULL.—For conspicuous gallantry and devotion to duty in helping under continuous shell fire to dig out several men who had been wounded and buried. He attended men under conditions which demanded considerable nerve and determination.

Capt. JOHN VICTOR LIVINGSTONE GRANT.—For conspicuous gallantry and devotion to duty when his ambulance was attacked on the march by enemy aeroplanes. A large ammunition dump at the side of the road was exploded, igniting a lorry loaded with petrol, and the fire spread to the ambulance wagons. He immediately collected men and for two hours worked coolly and fearlessly near the exploding dump, under repeated bombing attacks from aircraft, tending and removing the wounded.

Capt. ROBERT LAWSON.—During several days' operations he worked continuously at high pressure under heavy shell fire. His energy and care for the wounded under the most difficult circumstances were beyond all praise, and he showed great gallantry and devotion to duty in organising his bearers and collecting wounded from a heavily-shelled area, thereby saving many lives.

Capt. BENJAMIN LYON, Canadian A.M.C.—For conspicuous gallantry and devotion to duty in action. After a charge by two squadrons up a road this officer followed on foot and attended and evacuated the wounded under heavy artillery and machine-gun fire, remaining there until all the wounded were brought in.

Temp. Capt. HENRY LESLIE MESSENGER.—For conspicuous gallantry and devotion to duty while an exceptionally heavy shoot was being carried out on a battery. He crossed 400 yards in the open under heavy barrage to attend to a wounded man. On his way he was knocked down by an exploding shell, but in spite of this he proceeded with his duties. He showed great grit and determination.

Capt. WALTER JAMES ELLIS MINGIE, Canadian A.M.C.—For conspicuous gallantry and devotion to duty during an attack. He maintained close touch with all the regiments, and under heavy shell and machine-gun fire he evacuated all casualties with wonderful rapidity. Hearing that an officer was seriously wounded in the front line trench, he immediately went forward and succeeded in dressing and removing him. He showed the greatest coolness and resource throughout.

Temp. Capt. STANLEY ANDREW WOOLLASTON MUNRO.—He organised his advanced dressing station and stretcher-bearing parties under very difficult circumstances, and when it was found necessary to withdraw the battalion to the original position he reorganised the stretcher-bearers and himself took up a post in the front line where he could better render assistance to the wounded. He also went and bandaged a wounded man who was lying in a position that was being shelled and had him conveyed to safety. Throughout his cheerfulness, energy, and disregard for his own personal safety had a most inspiring effect on all.

Temp. Capt. ANDREW NEILSON.—For conspicuous gallantry and devotion to duty when a number of wounded were left after a cavalry charge. He took two light ambulances and a bearer party right up to the front line and cleared five wounded lying out in front. This was done under continuous machine-gun fire directed on the road in the dark. He showed great courage and initiative.

Temp. Lieut. WILFRED PATON PHILIP.—During an attack he showed great gallantry in attending to a large number of wounded. He three times had to move his dressing station on account of shell fire, but stuck to his duties with great determination and saved many lives.

Temp. Capt. (acting Major) CLIVE JUSTIN HICKS SHARP.—For conspicuous gallantry and devotion to duty. He most ably supervised the evacuation of wounded during a rapid advance. Moreover, on hearing that one of the advanced dressing stations had been hit by a bomb, he at once went to the spot and helped with the wounded, and his coolness and energy were of the greatest assistance in reorganising the dressing station under shell fire, so that the evacuation of the wounded proceeded uninterruptedly.

Temp. Capt. JOHN PATRICK SHAW.—For conspicuous gallantry and devotion to duty. Under severe enemy shelling he carried on his work in the open, his aid-post affording neither space nor protection. He did invaluable service under most trying circumstances, as his was the collecting station both for his own battalion and for the brigade front. He showed magnificent energy and devotion to duty.

Capt. (acting Major) JAMES MARTIN SMITH.—For conspicuous devotion to duty when an enemy shell exploded an ammunition dump near his dressing station. He rushed to the spot, organised a rescue party regardless of exploding shells, and continued to attend to the wounded until all were removed to safety. He saved many lives by his gallant conduct.

Temp. Capt. ANDREW WILLIAM PALETHORPE TODD.—During an attack this officer, who was stationed at the advanced collecting post, behaved with great gallantry under the heavy artillery fire to which his post was subjected at frequent intervals during the day. He dressed and attended to large numbers of wounded men with unremitting devotion to duty, and also went forward under heavy fire with stretcher-bearers to the aid-posts, and by his able leadership rendered valuable service in evacuating the wounded.

Military Medal.

Dr. PHŒBE CHAPPLE, R.A.M.C., attached Q.M.A.A.C.—For gallantry and devotion to duty during an enemy air raid. While the raid was in progress Dr. Chapple attended to the needs of the wounded regardless of her own safety.

MENTIONED IN DESPATCHES.

In a despatch received from Sir Douglas Haig, dated July 20th, 1918, and dealing with the period following the actions in the vicinity of Cambrai in the first week of December, 1917, and leading up to the set-back to the Allies in March last, the following reference to the medical services is included:—

Much additional work, also under circumstances of unusual difficulty and danger, has necessarily been thrown upon the medical and nursing services. The conduct of the Royal Army Medical Corps and Medical Corps of the Overseas Dominions has again been beyond all praise, while the efficient organisation of the medical services as a whole proved itself fully equal to the occasion. I take this opportunity to acknowledge the lasting debt due in this connexion to Lieutenant-General Sir A. T. Sloggett, K.C.B., K.C.M.G., K.C.V.O., K.H.S., until recently Director-General of Medical Services, with whom the work of the medical services has so long been identified.

Medical News.

UNIVERSITY OF CAMBRIDGE.—The following candidates have satisfied the examiners in both parts of the Examination in Sanitary Science:—

Andrew Grant, Captain, R.A.M.C.; Joan Hardy; William Athol Desmond King, Captain, R.A.M.C.; Aloysius Dominic MacMahon; Mary Helen Routledge; Hilda Mary Scarborough; Percy Stocks; Shankarlal Vaidya; John David Whitfield; and James Herbert Wright, Staff-Surgeon, R.N.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following candidates have passed the Triple Qualification Examinations:—

THIRD EXAMINATION.

John Stevenson, John Rorrison McCubbing, Agnes Macilwraith Hill, Thomas Poole, Veeravagu Kathiravelu Paramanayagam, Henry Aidan Newton, Daniel Augustine Dias, James Sydney Alexander Rogers, and Walter Granville Carew.

Pathology.—Hamish Russell Fisher.

Materia Medica.—Alexandra Mary Limont and Peter Fraser Fairley.

FINAL EXAMINATION.

Thomas Talmage Read, John Wilson Gaston, Rebecca Goodman, George Thomas Graham Boyce, Don Alfred Walpola, Anup Singh Narula, Apcar Galustian, Sylvester Henry Meiring, John Birchmans Bourke, Arthur Stanley Hughes, and Fergus Donald Yourell.

Medicine.—William Gibb, Victor Albert Rankin, and Krishna Abaji Deodhar.

Surgery.—Victor Albert Rankin.

Midwifery.—Thomas Hardie and William Gibb.

Medical Jurisprudence.—Alexander Forsyth Caddell, Mayberry Hugh Carleton, James Maxwell Adams McVey, Andrew Francis Brigimen, John Stevenson, and Thomas Poole.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—At a meeting of the College held on Oct. 17th the following gentlemen, having passed the requisite examinations between July 1st and 5th, were admitted Fellows:—

Thomas Hood Wilson Alexander, Jan Martimus Beyers, Edward Stanley Brentnall, Francis Davidson Cairns, Harold Liat Him Lim, Thomas Robert Gray Melrose, George Robertson, Cecil Michell Rolston, Baron Theodore Rose, Thomas Henry Sanderson-Wells, John Zacherias Truter, William Robert Elsteb Unthank, and Batukdeva Prasad Varma.

At the annual meeting of the College Dr. Robert McKenzie Johnston was re-elected President for the ensuing year.

DONATIONS AND BEQUESTS.—By the will of the late Dr. Louis Albert Dunn, of Gerrards Cross, Bucks, the testator left to Guy's Hospital the gold medal presented by London University when he took his degree as Master in Surgery, being the first of its kind ever won by a Guy's man; and the residue of his property in trust for his two brothers for life, with remainder to the survivor for life, with ultimate remainder to Guy's Hospital for the Medical School. The gross value of the estates is £68,000 and the net personalty £56,000.

THE BELL FUND.—Dr. S. A. Kinnier Wilson asks us to acknowledge a donation to the Dr. J. H. Bell Fund of £1 1s. from Dr. H. J. Norman. Subscriptions should be sent to Dr. Wilson, at 14, Harley-street, London, W.1.

MEDICAL SOCIETY OF LONDON.—A meeting of this society will be held at 11, Chandos-street, Cavendish-square, W., on Monday, Oct. 28th, at 8.30 P.M., when papers will be read on "Rheumatoid Arthritis": The Pathology, by Mr. T. S. P. Strangeways; the Treatment, by Dr. A. P. Beddard. Medical officers of the Allied Forces will be welcome at the meeting.

MEMORIAL TO THE LATE DR. FRANCIS MCKEE.—On Oct. 17th a portrait of the late Dr. Francis McKee, of Dromore, co. Down, was unveiled at the Cowan Heron Hospital, Dromore, and a memorial bed was presented to the institution in his memory. Both have been given by Dr. McKee's friends to commemorate his services as honorary surgeon to the hospital from its opening in 1900 to 1915.

THE annual general meeting of the Army and Navy Male Nurses' Co-operation will be held at 52, Welbeck-street, London, W., on Monday, Nov. 4th, at 4 P.M. The honorary treasurer's annual statement reports an improvement in the financial position of the Co-operation.

MEDICAL DEFENCE UNION.—Sir John Tweedy, LL.D., ex-President, Royal College of Surgeons of England, has been again re-elected President of the Medical Defence Union; Mr. Gunton Alderton re-elected honorary treasurer; and Dr. A. G. Bateman and Mr. W. E. Hempson re-elected secretary and solicitor respectively. There have been added to the Vice-Presidents Surgeon-Commander C. T. Baxter, R.N., and Surgeon Lieutenant Commander H. B. Hill, R.N., as representatives of the Navy Medical Staff; the sister Service has been well represented for some years. The annual general meeting was held on Sept. 19th, when the annual report was presented and adopted and the usual statutory resolutions passed unanimously. The work of the Union was reported by the President to have greatly increased owing to the war, and its services have been sought and greatly appreciated by members on active service who required advice and assistance in matters relating to their military appointments and their civil practices.

THE OPENING OF THE WINTER SESSION AT THE BELFAST MEDICAL SCHOOL.—The winter session opened on Tuesday, Oct. 15th, without any formal address at Queen's University, but at the hospital Dr. J. B. Moore gave an introductory address on the students' career and on problems of reconstruction, the solution of which he saw in the direction of coöperative effort, resulting in a life of reasonable comfort and prosperity.—At the Royal Victoria Hospital on Thursday, Oct. 17th, Colonel J. Sinclair, C.B., late Consulting Surgeon to H.M. Forces, gave an address to men and women students in the King Edward VII. Memorial Hall. He referred to the devotion and courage shown by nurses in the war, specially mentioning the sisters and nurses trained at the Royal Victoria Hospital Training School, who, with their superintendent, Miss Bostock, had received the award of the First Class Royal Red Cross, four other Royal Red Crosses, two Military Medals, and four mentions in despatches for services in India, Mesopotamia, Egypt, Salonika, and on the Western fronts. Colonel Sinclair concluded by referring to the shortage of doctors at the front. He urged that a determined effort should be made to fill the ranks, announcing that should a sufficient number of students, academically eligible, at once present themselves he believed the University would grant them a special examination for the purpose.

THE LATE ROBERT A. BUNTINE, M.B., C.M. MELB.—A popular member of the South African Union Parliament, Dr. R. A. Buntine, was among the victims of the torpedoing of the *Galway Castle* off Ushant last month. Dr. Buntine was returning to South Africa from England with his two daughters, aged 20 and 18 respectively. The elder one perished with her father; the younger was among the saved. Dr. Buntine was born in Melbourne 50 years ago, and migrated to Natal in 1893. He took part in the Boer War with the Natal Medical Corps, and went through the siege of Ladysmith, in connexion with which he was mentioned in despatches for distinguished service in the field. A South African correspondent writes: "The doctor was returned to the Union Parliament three years ago as the Member for Maritzburg South. He belonged to General Botha's South African Party, and the Premier spoke of him a sa 'true friend and great help and support.' A man of great kindness of heart, Dr. Buntine sheltered on his farm an old friend of Teutonic nationality at the time of the anti-German riots of 1915 following on the *Lusitania* tragedy. No one will ever know the number of the poor and needy whom the deceased Good Samaritan attended without fee or wish for reward, and even with cost of medicine. His death is deeply lamented in South Africa."

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Housing Bill.

Mr. HAYES FISHER (President of the Local Government Board) on Thursday, Oct. 17th, presented in the House of Commons a Bill designed "to confer further powers on county councils in relation to the provision of houses for persons in their employment or paid by them, and to the housing of the working classes." It was read a first time.

The Midwives Bill.

The Midwives Bill has received a third reading in the House of Commons. In Committee Clause 12, which repeals Section 9 of the Midwives Act, 1902, enabling county councils to delegate their powers to district councils, was carried by 60 votes to 38.

Naval and Military War Pensions Bill.

The Naval and Military War Pensions Bill, which was read a second time in the House of Commons on Tuesday, Oct. 22nd, deals with administrative matters and local War Pensions Committees. It was criticised in many details. Clause 7 lays down that if a disabled officer or man refuses or without reasonable excuse fails to submit himself for medical examination, or refuses to undergo the treatment prescribed for him in an institution or otherwise, his pension or allowance may be suspended. Sir WATSON CHEYNE took exception to this provision. Compulsory operations, he said, would require very serious consideration indeed. If the disability were not something which would imperil the man's life the matter should be left to his own free will and judgment without compulsion.

HOUSE OF COMMONS.

THURSDAY, OCT. 17TH.

Venereal Disease and Regulation 40 D.

Mr. LEES-SMITH asked the Home Secretary whether he could now state how many women had been arrested under the Defence of the Realm Regulation 40D; and in how many cases convictions had been obtained.—Sir G. CAVE replied: Up to Oct. 8th there had been 201 prosecutions under the regulation. Convictions had been obtained in 102 cases, in 51 of which the defendants pleaded guilty. Three other defendants were bound over or placed on probation, and six cases were under remand when the return was made.

Mr. LEES-SMITH: In view of the answer that in nearly one out of every two cases no conviction was obtained, may I ask whether any arrangement has been made to give compensation to the women who have been subjected to this examination?—Sir G. CAVE: I think that the return shows that the magistrates are very careful, and do not convict except in very clear cases.

Mr. DILLON: Will the right honourable gentleman undertake to give the House an early opportunity of discussing this abominable regulation?

Lord H. CAVENDISH BENTINCK: In view of the futility of this Order will the right honourable gentleman withdraw it altogether?—Sir G. CAVE: As a matter of fact, the regulation is being considered by a committee, which will report in due course.

Mr. H. SAMUEL: In view of the very widespread interest in this matter will my right honourable friend endeavour to expedite the report of the committee?—Sir G. CAVE: The committee has been asked to report as soon as possible.

Mr. DILLON: Will the right honourable gentleman allow the House an opportunity of discussing this matter before the committee reports, which may not be until after Christmas?—Sir G. CAVE: That is not a question for me, but in any case it would be very undesirable to have a discussion while the committee is considering the question.

Mr. PRINGLE: Can the right honourable gentleman give the House an assurance that the committee will report before the Prorogation?—Sir G. CAVE: I cannot, of course, do that. The committee has been asked to report as early as possible.

Mr. DILLON: I shall raise this question at the very earliest opportunity.

Mr. LEES-SMITH asked whether the terms of reference of the committee set up to inquire into the Defence of the Realm Regulation 40D were confined to the modification of the regulation or included also the question of its withdrawal.—Sir G. CAVE answered: The committee was appointed to consider the regulation and what modification (if any) should be made in its terms or in the procedure for enforcing it, and I do not think the committee would be precluded from considering the question of its withdrawal.

Mr. LEES-SMITH: As the committee is considering the question of the withdrawal of this regulation, and in view of the general hostility to it, will the right honourable gentleman have it suspended until the committee has reported?—

Sir G. CAVE: No. The Cabinet has already given a decision on that point.

Mr. ALDEN: If the committee reports against the regulation can the right honourable gentleman in his own person withdraw it?—Sir G. CAVE: I could not. It would have to be rescinded by Order in Council.

Housing in Ireland.

Mr. SCANLAN asked the Chief Secretary for Ireland whether the Government had prepared a scheme for the provision of suitable houses for the workers in the towns and cities of Ireland; whether the Treasury had been requested to support such a scheme; and when the Government would begin to carry out in Ireland a scheme to settle the housing problem.—Mr. SHORTT said in reply: I am not in a position to make any statement on the subject.

Mr. SCANLAN: Has the matter of housing engaged the attention of the right honourable gentleman at all?—Mr. SHORTT: Yes, to a very considerable extent.

Housing Scheme for Lanarkshire.

Mr. DUNCAN MILLAR asked the Secretary for Scotland what progress had been made with the additional housing scheme for Lanarkshire which was some time ago approved by the Ministry of Munitions and the Scottish Local Government Board, and the number of houses which had been allocated to each district.—Mr. MUNRO wrote in reply: Proposals, I understand, have been made by the Ministry of Munitions to the local authorities and are at present receiving their consideration.

MONDAY, OCT. 21ST.

Artificial Limbs for Discharged Soldiers.

Sir MONTAGUE BARLOW asked the Pensions Minister whether his attention had been called to the delay in obtaining repairs to the artificial limbs of discharged sailors and soldiers; whether, in view of the suffering and hardships entailed, he would consider the advisability of having such limbs standardised; and whether he could state how long it was likely to be before he is able to carry out his promise of issuing a spare limb to each man so that he would be able to substitute one while the other was being mended.—Mr. HODGE replied: My attention has been drawn to the delay. A recent instruction which enables local War Pensions Committees to authorise repairs (locally where possible) without previous reference to the Ministry will, it is hoped, obviate delay in minor cases, and, with regard to major repairs and the readmission of pensioners into limb-fitting centres, the increase in the number of beds at fitting centres from 972 in February, 1918, to 2196 in October will enable cases to be more expeditiously dealt with. It has not yet been found possible to standardise limbs, as no specimen brought to the knowledge of the expert Advisory Council has shown such advantages over any other as to warrant it being made the standard pattern. The promise to issue a spare limb to all cases will, I hope, be carried out within a reasonable period, but clearly the primary fitting of limbs must be the first consideration. It is proposed to supply a light provisional peg leg of fibre or other prescribed pattern in all cases for use in emergency. This should obviate inconvenience to men until the spare limb can be provided.

Indian Medical Service.

Colonel YATE asked the Secretary of State for India whether he had received a reply from the Government of India regarding the position of officers in the Indian Medical Service; and what increase of pay had been granted to these officers so as to ensure an efficient and contented Indian Medical Service.—Mr. MONTAGU answered: I regret I am not in a position to announce a decision on this question, regarding which I am in telegraphic correspondence with the Government of India. I am doing all I can to expedite the settlement of what I recognise to be an urgent and important issue, and hope to be in a position to make a statement within a week or two. I will let my honourable and gallant friend know when a decision has been reached.

TUESDAY, OCT. 22ND.

Serious Outbreak of Rabies.

Answering Sir W. BULL, in regard to the spread of rabies amongst dogs in the counties of Devon and Cornwall, Mr. PROTHERO (President of the Board of Agriculture) stated that in all 40 cases of rabies had been confirmed since Sept. 7th—35 in Devon and 5 in Cornwall. Of these no fewer than 29 occurred in the county borough of Plymouth. Seven dogs, which had been in contact with dogs at a place where an outbreak had occurred, had been taken to places outside Devon and Cornwall. These had now all been traced and isolated. It would be seen that grave risk of the spread of this disease to other parts of the country had been thus incurred. The right honourable gentleman proceeded: Human life is at stake in this matter. At least 21 persons are known to have been bitten by these rabid dogs, nine being children, and any person who fails to assist by giving information required by my Department will incur a very grave responsibility should the disease spread to other districts.

An HON. MEMBER: Have any deaths resulted from the bites of these dogs?—Mr. PROTHERO: No, not up to the present.

Fazakerley Sanatorium.

Mr. PENNEFATHER asked the Parliamentary Secretary to the Local Government Board how many discharged men there were in Liverpool who were suffering from tuberculosis caused or aggravated by military service, and unable to secure proper treatment owing to lack of sanatorium accommodation; and what steps would be taken to provide sufficient accommodation.—Mr. WALSH replied: I am informed that the number, which varies from day to day, is approximately 140. As to the provision of further accommodation, my right honourable friend has been taking all practicable steps to expedite the completion of the Fazakerley Sanatorium, and has reason to hope that it will be ready for the reception of patients within the next two or three months.

WEDNESDAY, OCT. 23RD.

Ministry of Health.

Mr. BOOTH asked the Chancellor of the Exchequer whether communications reached him from the Friendly Societies and trade-unions expressing opposition to any proposed Ministry of Health and local government which would place the health insurance department in association with the Poor-law administration, and what answer he had given thereto.—Mr. BONAR LAW replied: I am informed that resolutions have been received from these societies, but I hope that when the Bill has been discussed this opposition will not be maintained.

MEETINGS OF SECTIONS.

Monday, Oct. 28th.

ODONTOLOGY (Hon. Secretaries—F. N. Doubleday, G. Paton Pollitt, J. Howard Mummery): at 7.30 P.M.
Presidential Address by Mr. G. G. Campion.
Casual Communication by Mr. George Northcroft.

Friday, Nov. 1st.

LARYNGOLOGY (Hon. Secretaries—Frank A. Rose, Irwin Moore): at 4 P.M.
Cases and Specimens will be shown by:—
Mr. Somerville Hastings, Mr. Woakes, Mr. Hunter Tod, Mr. J. Gay French, Dr. Irwin Moore, Dr. Dundas Grant, Dr. Andrew Wylie, and others.

MEDICAL SOCIETY OF LONDON, 11, Chandos-st., Cavendish-sq., W.
MONDAY, Oct. 28th.—8.30 P.M., Papers on Rheumatoid Arthritis:—Mr. T. S. P. Strangeways: The Pathology; Dr. A. P. Beddard: The Treatment.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
FRIDAY, Nov. 1st.—5 P.M., Museum Demonstration:—Prof. A. Keith: Bone Setting—Ancient and Modern.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Clinics each week-day at 2 P.M., Wednesday, Friday, and Saturday also at 10 A.M.
(Details of Post-Graduate Course were given in issue of Sept. 27th.)

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Out-patients each day at 2.30 P.M.

NATIONAL ASSOCIATION FOR THE PREVENTION OF CONSUMPTION AND OTHER FORMS OF TUBERCULOSIS, in the Large Hall, 20, Hanover-square, W. 1.
TUESDAY, Oct. 29th.—4 P.M., Address:—Prof. S. M. Gunn: Tuberculosis Propaganda Work in France (illustrated by lantern-slides).

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.
Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—
WEDNESDAY, Oct. 30th.—4 P.M., Lecture IV:—Lieut.-Col. L. W. Harrison, M.B., D.S.O.: The Prevention and Abortive Treatment of Venereal Disease.

Notes, Short Comments, and Answers to Correspondents.

RACIAL RECONSTRUCTION AND THE PROPOSED MINISTRY OF HEALTH.

SUMMING up the principles which should govern the formation of a Ministry of Health, Dr. C. W. Saleeby, in a lecture on the above subject delivered at the Royal Institute of Public Health, London, on Oct. 16th, said that to learn, to teach, to guard, and to help must be the watchwords. The first heading would embrace a permanent anthropometric department, which would not only deal with physiology and anatomy, but include, as far as possible, a survey of the psychological factors of mind, while something should be done in regard to the selection of proper vocations for the people. There should also be a general up-to-date registry of births and deaths, with information respecting the living, and perpetual medical research. In part at least the Ministry of Health should control the instruction of all those directly concerned with the various aspects of health and healing, while the general public must also be taught if such a Ministry was to be an organisation appropriate to a free people. A watch should be kept on our weaknesses, prejudices, and preferences in regard to food, drink, and other matters, and finally help given by special departments for mothers and babies, and for recreation. We were, he suggested, well on the way to the conquering of Mars and Bacchus, and the next enemy that would have to be dealt with was Mammon. Bradford, which was credited by the lecturer with making so much money that the people did not know what to do with it, was a model city with regard to the provision for mothers and babies, yet the death-rate was 14·6 and the birth-rate 13·2. The logical deduction from these figures was that Bradford was dying out, the reason being that home life had been destroyed. So long as mothers went out to work there were no homes, but the only factor of national safety was the mother in the home and the baby at her breast. Objectives for a Ministry of Health Dr. Saleeby sees in protection from racial poisons, diachylon of lead, alcohol, and, most important of all, the parasite of syphilis.

HOW TO FEED THE FAMILY.

THE Ministry of Food has issued to the public a pamphlet (F.S.B. 27) containing a series of dietaries on which, with extreme economy and the avoidance of waste, health and efficiency may be maintained. Three dietaries are given in detail which work out at a weekly cost per "man" of 14*s.* 10*d.*, 10*s.* 6*d.*, and 7*s.* 5*d.*, or for a family consisting of a man, his wife, and four children from 8–16 years of age at £3 14*s.* 1*d.*, £2 12*s.* 7*d.*, and £1 17*s.* respectively. The pamphlet has been drawn up under the supervision of Professor E. H. Starling, whose name is sufficient guarantee for the accuracy of the physiological value of the foodstuffs in the quantities suggested. The recipes, too, appear to have been well selected and to bear the impress of the practical cook. The pamphlet is, of course, applicable to present conditions, and to present conditions only. With pre-war wages and pre-war prices no married worker was likely to spend £3 10*s.* to £4 a week on food for himself, his wife, and four children. We may recall the figure of 4*s.* 4*d.* given by Mr. B. Seebohm Rowntree in his recent book, "The Human Needs of Labour," as the weekly cost per "man" of a minimum dietary consistent with health on the basis of retail prices ruling in York in July, 1914. Between that date and July, 1918, the date at which the prices in the Ministry of Food's pamphlet are reckoned, the average price of foodstuffs had gone up some 120 per cent., which would bring Mr. Rowntree's figure to 9*s.* 6*d.* Mr. Rowntree admits that his standard errs on the side of economy. Dietary I. of the Ministry of Food is doubtless a little generous, and Dietary III. more than a little skimpy. Dietary II., being the happy mean, at the convenient figure of 10*s.* 6*d.* a week, deserves special attention. Copies of the pamphlet may be obtained gratis on application to the Despatch Section, Ministry of Food, 35, Park-street, London, W. 1.

PUBLIC EULOGY OF THE MEDICAL PROFESSION.

To the Editor of THE LANCET.

SIR,—Referring to the note with the above heading in THE LANCET of June 22nd it may be of interest to recall a somewhat similar eulogy in this small colony of Fiji. A good many years ago the writer was asked to see an elderly Fijian chief afflicted with a painful suppurating external pile. This was treated in the usual way to his great eventual content, subsequent rectal examination being made to determfne if internal piles were also present. The old gentleman subsequently described what had occurred, to the resident magistrate, in the following words: "The doctor came and removed my entire intestines, placed them

on a plate (which, as your note says, is apparently necessary, and is so out here also), washed them, and returned them to their place." He then turned to his native henchman for confirmation of the story, and obtained loyal support for it.

I am, Sir, yours faithfully,

Suva, Fiji, Sept. 3rd, 1918. G. W. A. LYNCH.

THE AUGWIN DENTAL EMERGENCY OUTFIT.

THIS practical little dental emergency outfit has been designed by Mr. Augustus Winterbottom, F.R.C.S., L.D.S., for the use of sailors and soldiers on active service, and for general practitioners and those who are unable to obtain the services of a dentist. It consists of a neat metal case, measuring 5¼ × 4¼ × 3 in., of which the contents are as follows: A mouth mirror, probes, excavator, scaler, and stopper for the insertion of temporary fillings and the treatment of carious teeth, together with bottles of dental plasters and counter-irritant solutions for the relief of pain. It also contains disinfectant tablets for the treatment of the different diseases of the gums, guttapercha, fluid temporary filling, and a suitable supply of cotton wool, rolls and pellets, with simple directions for use. As these directions are remarkably clear and explicit, and as, with the exception of the counter-irritant solution, which is suitably labelled, there is nothing likely to prove injurious in the hands of the unskilled, the outfit should, with regard to the Army, enable the officer or N.C.O. to give relief to his suffering comrades. It has happened in a great number of cases that, owing to the shortage of dentists near the front line, soldiers suffering from toothache have had to endure much pain before they were able to return to the base, where lay their only chance of receiving the necessary treatment. In such circumstances this little outfit should prove to be of great value. It should also do good service in the Navy, for the men are often at sea for long periods at a time and in circumstances when the mental strain is sufficiently severe, without the addition of physical torture. It actually happened that, in the early days of the war, an admiral, with all his responsibilities, had to suffer with an exposed nerve on either side of his mouth for three weeks before he could obtain proper dental treatment. The outfit is being made up by the Dental Manufacturing Co., Alston House, Newman-street, London, W. 1.

ACCURATE CLINICAL THERMOMETRY.

REFERENCE was made last week in our annotation columns to the Order issued by the Ministry of Munitions of War demanding that on and after Oct. 21st, 1918, no person shall sell, offer for sale, supply, or deliver any clinical thermometer which has not been tested, approved, and marked in accordance with rules made by the Controller of Glassware Supply on behalf of the Minister of Munitions, in consultation with the Local Government Board and the Department of Scientific and Industrial Research.

We now understand that no steps will be taken to enforce the Order until Nov. 21st. The period during which clinical thermometers will be approved if they show an error of no more than 0·4° F. will be extended so as to include those received at the National Physical Laboratory on or before that date. This extension, however, only applies to stocks held on the date of the Order (Oct. 11th) by dealers other than manufacturers.

A HOME SCHOOL WANTED.

To the Editor of THE LANCET.

SIR,—Can any of your readers recommend a home school, preferably on the East Coast, where a girl of 15, subject to mild epilepsy, would be received for general education?

I am, Sir, yours faithfully,

R.N. Hospital, Haslar, Oct. 23rd, 1918. HILDRED CARLILL.

Practitioner.—It is a fact that in all large establishments some amount of clerical and organising work falls to the medical men. We fear this is part of the system under which, at any rate in older days, officers of the R.A.M.C. as they rose in seniority became more of organisers and less of clinicians.

Vacancies.

For further information refer to the advertisement columns.

Bexley, Kent, London County Mental Hospital.—Asst. M.O's. 7 gs. a wk.
Birmingham City Sanatorium and Anti-Tuberculosis Centre.—Jun. Asst. M.O. £350.
Birkenhead Union.—Sen. and Jun. Res. Asst. M.O's. £350 and £300
Bradford.—Temp. Asst. Sch. M.O. £8 8s. per week.
Bristol Royal Infirmary.—H.P. and H.S. £120.
Dagenham (Temporary) Sanatorium.—Res. M.O. £300.
Dorchester, Dorset County Council Education Committee.—School Dentist. £350.
Greenwich Union Infirmary.—Asst. M.O. £300.
Hastings, East Sussex Hospital.—H.S. £250.
Hospital for Consumption and Diseases of the Chest, Brompton.—H.P. 30 guineas. Also Asst. Res. M.O. £100.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. £100.
Huddersfield County Borough.—Female Asst. M.O.H. £400.
Kirkburton, Storthes Hall Asylum, Huddersfield.—L.T. £7 7s. per wk.
Leeds City Public Health Department.—Female Med. Asst. £400.
London Temperance Hospital, Hampstead-road, N.W.—Medical Registrar. 40 guineas.
Manchester, Crossley Sanatorium, Delamere Forest, Cheshire.—Asst. M.O. £300.
Manchester Northern Hospital for Women and Children, Park-place, Cheetham Hill-road.—H.S. £150.
Nelley, Welsh Military Hospital.—M.O. £400.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Asst. Res. M.O. £250. Also H.P.'s. and H.S.'s. £50, and (in one case) £100.
Newcastle-upon-Tyne, University of Durham College of Medicine.—Lect. Psych. Med.
Plaistow Fever Hospital.—Asst. M.O. £300.
Plymouth, South Devon and East Cornwall Hospital.—H.P. £200.
Queen Charlotte's Lying-in Hospital, N.W.—Asst. Res. M.O. £60.
Reading, Royal Berkshire Hospital.—H.P. £250.
Rhondda Urban District Council.—Dent. S. £350.
Royal London Ophthalmic Hospital.—Deputy Bacteriologist. £120.
Salford Royal Hospital.—H.P. £250. H.S. £200. Jun. H.S. £150.
South London Hospital for Women.—Female Clin. Asst. £1 1s. per attendance. Also Anæsth. 10s. 6d. per attendance.
Stepney Tuberculosis Dispensary.—M.O. £500.
Wakefield, Clayton Hospital.—H.S. £250.
Western General Dispensary, Marylebone-road, N.W.—Hon. Oph. S.
West London Hospital, Hammersmith-road, W.—H.S.
Whitechapel Dispensary for the Prevention of Consumption, Whitechapel, E.—M.O. £500.
Wilts County Council.—L.T. for M.O.H. 14 guineas per week.

APPOINTMENTS are vacant for a Medical Referee under the Workmen's Compensation Act for County Court Circuit No. 6 (St. Helens and Widnes) and County Court Circuit No. 7 (Birkenhead and Runcorn). Applicants, who should reside in the respective neighbourhoods, should communicate with the Private Secretary, Home Office, not later than Nov. 6th.

Births, Marriages, and Deaths.

BIRTHS.

FOOT.—On Oct. 15th, at Rydal, Crawley Down, Sussex, the wife of Captain T. J. Foot, R.A.M.C., of a son.
ILOTT.—On Oct. 16th, at Seaton, Devon, the wife of Captain Cyril H. T Ilott, R.A.M.C., of Bromley, Kent, of a daughter.
KENNEDY.—On Oct. 17th, the wife of Major C. M. Kennedy, F.R.C.S., R.A.M.C., of a son.
SAWYER.—On Oct. 14th, at Farquhar-road, Edgbaston, Birmingham, the wife of Lieutenant-Colonel J. E. H. Sawyer, R.A.M.C., of a son.

MARRIAGES.

MATHEWSON—HAMMOND.—On Oct. 16th, at West Ham Parish Church, George Douglas Mathewson, M.B., F.R.C.P.E., Temporary Major, R.A.M.C., to Alice Henrietta, second daughter of Captain and Mrs. Hammond, Forest Gate, Essex.

DEATHS.

FINCH.—On Oct. 8th, at the Officers' Hospital, Basra, Mesopotamia, Captain George Finch, R.A.M.C. (T.F.), late of Ipswich, of pleuro-pneumonia.
NIGHTINGALE.—On Oct. 17th, at Sloane-street, suddenly, of pneumonia, Percy Athelstan Nightingale, M.D. Edin.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

MANAGER'S NOTICES.

THE LANCET is published weekly, price 10*d.*, by post 10½*d.* inland, and 11½*d* colonies and abroad.

An Address
ON
SPIROCHÆTOSIS ICTEROHÆMORRHAGICA.

Delivered before the Section of Medicine of the Royal Society of Medicine

BY MAJOR-GENERAL SIR BERTRAND DAWSON, M.D.LOND., F.R.C.P.LOND., G.C.V.O., C.B.,
ARMY MEDICAL SERVICE; PHYSICIAN-IN-ORDINARY TO H.M. THE KING; PHYSICIAN TO THE LONDON HOSPITAL.

THE spirochætes form a large group of unicellular organisms, most of which are harmless saprophytes, and are commonly found in the various genera of shell fish. Those proved to be pathogenic are few, though increasing in number, and belong to the smaller forms. It seems to be established that they multiply by longitudinal or transverse division, but conjugation has not been established. The spirochæte of tick fever has been shown by Leishman to give rise to coccoid forms which appear to be able to produce the disease, and resembling, it may be, in their attributes bacterial spores. Whether spirochætes belong to the vegetable or animal kingdom—whether they are bacteria or protozoa—is a question of academic interest for determining which criteria appear to be lacking.

DESCRIPTION OF ORGANISM: CULTIVATION AND AGGLUTINATION.

Spirochæta icterohæmorrhagiæ, discovered by Inada and Ido in 1914. The organism varies in length from 4μ to 25μ with an average of 8μ to 9μ. The ends are sharp and pointed, and in many cases hooked. Martin, Pettit, and Vaudremer have described flagella, terminally placed, and of varying length and ending in circular knobs, the significance of which is unknown. (Fig. 1.) The organism shows irregular undulations, usually composed of two to three large, or four to five smaller, waves. (Fig. 2.) Rarely forms in which the waves are more numerous and regular occur, thus resembling *T. pallidum*. Other variations in shape are met with: round or oblong granules, three or four in number, may appear within some forms.

Cultivation.—*S. icterohæmorrhagiæ* was first cultivated by Ito and Matsuzaki, who employed the method of Noguchi, guinea-pig kidney replacing that of the rabbit usually employed. The cultures were made from the blood or liver-

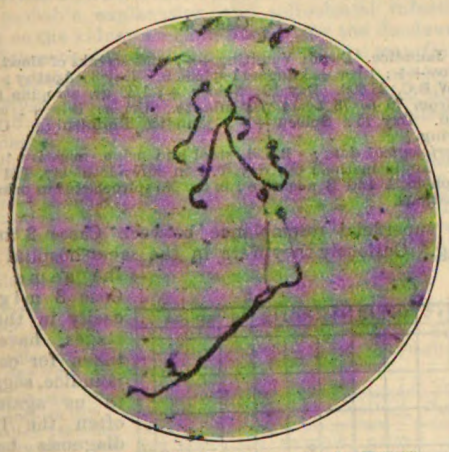

FIG. 1.—*Spirochæta icterohæmorrhagiæ* (Pettit).

pulp of an infected guinea-pig, and incubated at a temperature of 22°–25° C. They noticed that growth commenced as a rule in from three to seven days, and that the first generation lived from three to six weeks, the lives of succeeding generations being rather shorter. These same workers have since shown that this spirochæte can be grown in various media, liquid and solid—blood agar and gelatin, human serum, diluted ox serum, and ascitic fluid.

Martin and Pettit advise the use of diluted rabbit serum (1 in 5 of normal saline) or diluted ox serum (1 in 9 of normal saline). The medium is covered with a layer of sterile paraffin and no tissue is added. The optimum temperature is about 27° C., but growth occurs at temperatures varying between 22° C. and 32° C. Growth is at its height about the tenth day in primary culture, and at the fourth to sixth day in subsequent subcultures, and usually at the end of three weeks the culture is dead. Subcultures should be made at the height of growth by the inoculation of fresh tubes of media with 0·5 c.cm. of the living cultures. No growth, or only a feeble growth, occurs in the presence of contamination.

The organism has considerable vitality and will remain active in tap-water exposed to wintry weather for many days,

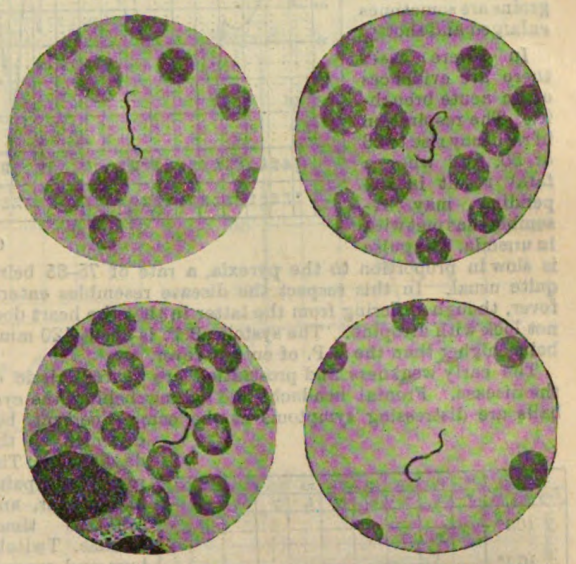

FIG. 2.—*Spirochæta icterohæmorrhagiæ* in blood of guinea-pig experimentally infected (Bedson).

but it has a curious way of suddenly dying out under good conditions and without any apparent reason.

Agglutination.—It was noted by Martin and Pettit, during the course of their work on the preparation of an antiserum for spirochætal jaundice, that this antiserum was capable of agglutinating the spirochætes. The antiserum therefore possessed, in addition to the spirochæticidal immune bodies, a specific agglutinin. In view of this fact they examined the sera of convalescents for the presence of agglutinins, and were able to show that here also the sera possessed the power of clumping the spirochætes. Since it is possible to grow this spirochæte with comparative ease, we are now in possession of an additional diagnostic test of value.

The cultures used must be at the height of growth and must show no clumping of spirochætes. Unless the culture be very rich macroscopic agglutination is not obtained; the test therefore has to be done microscopically with the aid of a dark-ground condenser. Martin and Pettit have shown that this agglutinating power of the sera of convalescents may rise to a titre of 1 in 500 or 600, whilst normal sera and the sera of syphilitics are without effect on the spirochæte. These agglutinins appear in the blood about the third week of the disease, at the same time as the other immune bodies.

CLINICAL MANIFESTATIONS.

The disease has more often a sudden than a gradual onset, and manifests itself by shivering, head and body pains, great prostration, vomiting, and diarrhœa. The temperature rises quickly to 102° F. or higher. During the succeeding three or four days the conjunctivæ become injected, and herpes, which is liable to become hæmorrhagic, appears on the lips in about 40 per cent. of the patients. Bleeding occurs in most of the severe cases, but uncommonly in the mild ones. It may come from the nose, lungs, stomach, bowel, or as a purpuric rash. Early in the illness a slight hæmoptysis is a valuable diagnostic sign. It is to be noted that hæmorrhage often precedes jaundice in order of appearance.

The jaundice usually appears on the fourth or fifth day, but may be as early as the second and as late as the seventh day. It reaches its height about the tenth to twelfth day. In some cases it is intense, and the skin takes the greenish hue met with in complete obstruction of the common bile-duct. Constipation is marked. The stools may become clay-coloured, though in most cases a small quantity of bile gives them a light brown colouration. Tenderness in the upper abdomen is

usual. The tongue is furred and brown. The liver is frequently enlarged to the extent of two or three fingers below the costal margin. The spleen is not palpable. The gland is in the axillæ and groins are sometimes enlarged and shotty.

In severe cases there are evidences of an acute bronchitis. The respiration in rate may rise to 28 or 30, and when a fatal result is impending may resemble that met with in uræmia. The pulse is slow in proportion to the pyrexia, a rate of 75–85 being quite usual. In this respect the disease resembles enteric fever, though differing from the latter in that the heart does not lock with atropine. The systolic B.P. is about 120 mm., being higher than the B.P. of enteric fever.

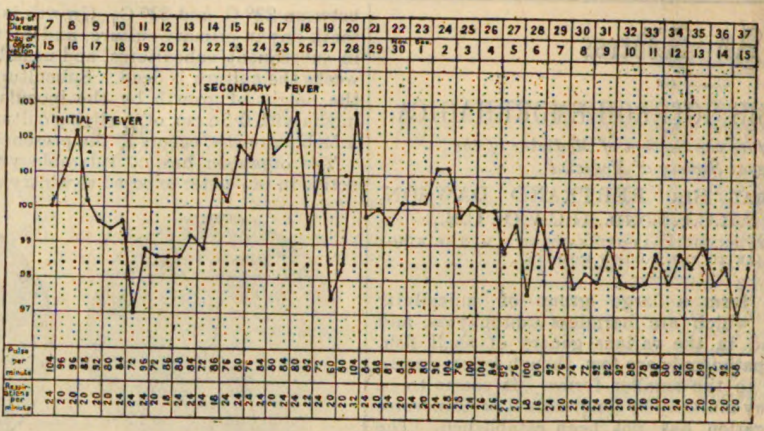
The early weakness and prostration are characteristic of the disease. Frontal headache and aching behind the eyeballs are distressing symptoms at the commencement, but diminish as the days pass. The muscular pains last longer, and are at times intense. Twitchings and convulsions may precede or accompany the coma of the fatal cases.

The urine contains bile in abundance, which may persist for four to five weeks. Albumin is usually present, and may reach a sixth; casts—hyaline, epithelial, and granular—are common. Some French authors lay stress on the evidences of renal insufficiency.

The course of the illness varies with the severity of the disease. In the acute case an irregular type of pyrexia persists for 10 to 14 days, and ends by lysis. In some instances there is a secondary rise of fever about the beginning of the third week, which is difficult to explain, since there is no accompanying exacerbation of symptoms or increase of jaundice. The jaundice will reach its height about the tenth day, and this often coincides with the fall of the temperature. In other cases the temperature will fall earlier, while the jaundice is still deepening. Convalescence is slow, but recovery is complete.

ILLUSTRATIVE CASES.

The following cases illustrate various types of the disease and show how the brunt of the morbid process does not always fall on the same organs.

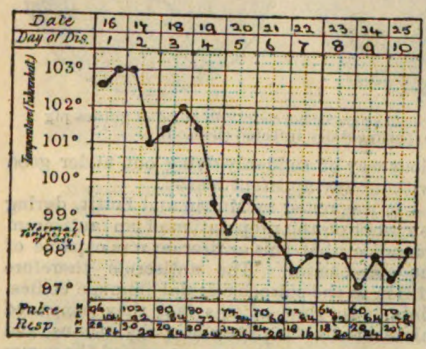


CASE 1.

CASE 1 (see chart).—Aged 38. Onset sudden, with vomiting. Day 3: Dark urine. Day 4: Drowsy; ill; reported sick. Day 7: Brown tongue; jaundice ++; epigastric tenderness. Liver + two fingers; spleen 0. Urine: albumin, bile, casts. Stools contained some bile. Blood: R.B.C. 5,200,000; W.B.C. 13,000. Day 7 to 18: Toxic; jaundice ++. Day 19: Gall-bladder drained (operation). Day 22: Jaundice less; condition improved. Day 32: Convalescent.

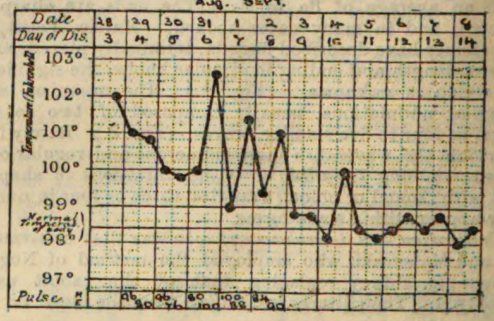
Not all cases of this disease conform to the foregoing picture; many are mild and less defined in their manifestations, and therefore more difficult of detection.

CASE 2. *Spirochætosis (mild)* (see chart).—Sudden onset; pains head and body; vomiting. Day 6: Suffusion of conjunctivæ; slight jaundice; liver 0; spleen 0. Day 9: Jaundice ++; drowsy. Day 10: Condition improving. 1/30 gr. atropine increased heart from 60 to 90 beats per minute. W.B.C. 8500. Day 12: Typical spirochætes found in urine.



CASE 2.

CASE 3. *Enteric jaundice* (inoculated against "T"). (See chart).—Sudden onset; lassitude ++; headache. Day 2: Generalised pains.

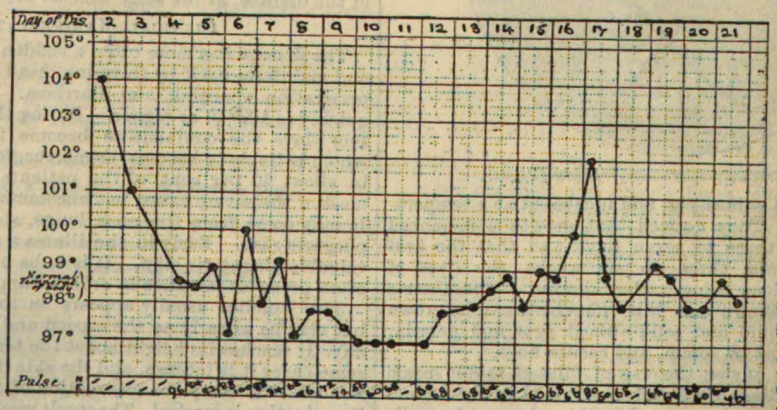


CASE 4.

Day 4: Jaundice. Day 5: Vomiting ++, with streaks of blood. Day 6: Jaundice ++; liver + 3 fingers; spleen 0. Day 8: Apathy; jaundice ++; W.B.C. 23,800. Day 10: Spleen +; 1/30 gr. atropine increased heart from 70 to 76 beats per minute. Urine: Bile +; casts; no albumin. Day 15: Spleen ++; jaundice diminishing. Condition improving.

Bacteriological data: Blood, stool and urine, negative to enteric group. Agglutination: 8th day, T. 1 in 3675; 16th day, T. 1 in 2822. Paratyphoid A and B negative 1 in 5. No spirochætes in urine in two examinations.

The superficial resemblance between Cases 2 and 3 is striking. Curiously they were in the same hospital and at the same time. Case 3 might so easily in the early stages have been taken for catarrhal jaundice, suggesting to us again how often the latter diagnosis has disguised enteric fever. The acute onset in this case is no unusual occurrence, for the acute onsets of enteric have been as frequent as the gradual ones. Apart from the bacteriological evidence the contrasts lie in the spleens, the conjunctival suffusion

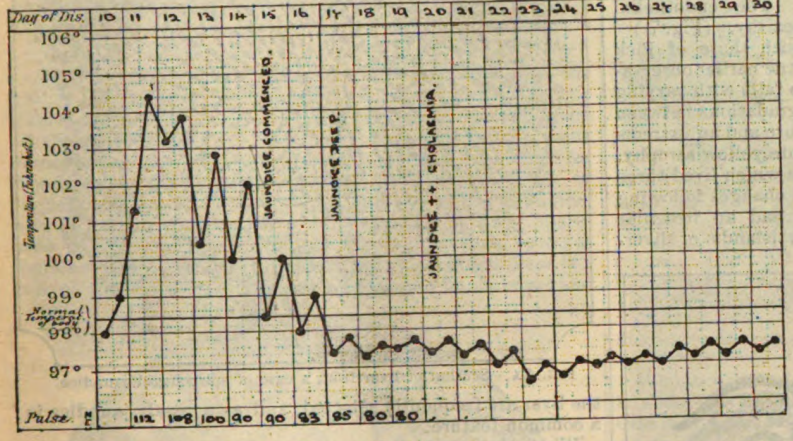


CASE 3.

and the atropine reactions. It might be urged that the W.B.C. in Case 3 should have been decreased, but in our experience leucopenia in enteric is by no means a constant feature.

Spirochætosis without jaundice.—Cases 4 and 5 illustrate this variety.

CASE 4 (see chart).—Onset sudden; feverish; generalised pains; lassitude +, giddiness. Day 3: Cough; herpes labialis. Day 4: Spirochætes in blood; pains continue. Day 10: Patient improving. Day 14: Typical spirochætes in urine.



CASE 6.

CASE 5. (*No jaundice.*)—Sudden onset; headache; body pains; photophobia; vomiting. Day 1: T. 104·2°; patient very ill. Days 2-5: Conjunctival suffusion; herpes labialis; vomiting +; no hæmorrhages. Day 14: Convalescence. Day 20: Relapse of fever and pains.

Inoculated guinea-pig developed jaundice. Spirochætes in patient's urine until the end of the ninth week.

CASE 6. *Nephritis in association with jaundice.* (See chart.)—Onset and early days: Body pains; mild headache; transient œdema. Urine: albumin and blood. Day 10: Looked ill. Urine: albumin, blood and casts. Day 11; Fever; urine as before. Day 15: Jaundice faint. Day 17: Jaundice deep. Urine: blood 0; albumin, trace. Days 17 to 30: Weak; wasted; drowsy; cholæmic. Picture resembled spirochætosis. Slow recovery.

Bacteriological data: Enteric negative. Typical spirochætes in urine on three occasions.

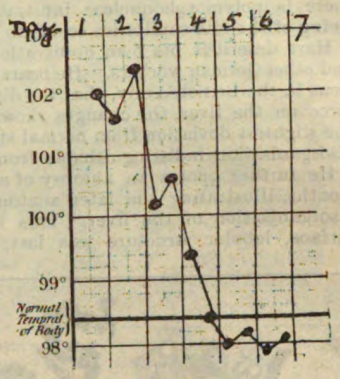
The interesting question arises, Did spirochætal infection happen to follow close on the heels of trench nephritis or did it cause the whole illness? The latter would seem to be the more probable explanation, the spirochætal infection first falling on the kidney and later attacking the duodenum or liver and thus producing the more usual clinical manifestations. The pathological findings in the kidneys are sometimes in keeping with a nephritis having existed during life.

Cases 7, 8, and 9 illustrate severe forms of the disease ending in death.

CASE 7.—Onset: Vomiting; pains in leg; fever. Day 3: Hæmatemesis (½ pint). Day 4: Ill; drowsy. Day 7: Jaundice rapidly ++. Day 10: Jaundice +++; abdominal distension; slight cough; bloody sputum. Liver + 3 fingers; spleen 0. Urine: Bile +; albumin +; no casts. Stools clay. R.B.C. 3,000,000; W.B.C. 20,000. Day 14: Drowsy; weak. Day 20: Temperature normal; jaundice less. Days 22 to 29: Drowsiness ++; picture of diabetic coma; jaundice diminishing; general clonic convulsions on 27th day; death in coma.

CASE 8.—Onset acute: pains; repeated vomiting; very ill; vomiting continued till the 14th day. Jaundice appeared 5th day. Liver + 2 fingers; spleen 0. Urine: Albumin trace; casts ++. Stools almost clay-coloured. Blood: W.B.C. 22,500. Drowsy throughout; died on 14th day from toxæmia.

CASE 9 (see chart).—Onset: Head and body pains, weakness, chilliness. Temperature 102°. Days 2 and 3: Repeated vomiting. Day 3: Herpes labialis; jaundice. Day 4: Temperature normal; jaundice markedly increased; liver and spleen not palpable; patient much worse. Day 5: Hæmatemesis; albumin ++, epithelial and erythrocytic casts, no spirochætes; dry brown tongue; tonic convulsions; general condition grave. Day 6 and onwards: Epistaxis, hæmatemesis, melæna, purpura. Guinea-pig inoculated seventh day; negative. Day 12: Death from toxæmia and anæmia. Urine contained characteristic spirochætes.



CASE 9.

PATHOLOGY.

I will pass at once to the morbid appearances of the two last cases, Nos. 8 and 9.

The mucous membrane of the duodenum was very œdematous and congested, its colour resembling a dark-blue plum. Round the orifice of the bile-duct was an area about the size of a florin, slightly raised above the level of the surrounding mucous membrane, and red and injected. In the centre of this area was the ampulla, swollen and congested. The above features were seen, though in a less degree, in the stomach and first three feet of the jejunum. The rest of the intestines was normal in appearance. At the edge of the lesser omentum and about the bile-ducts were numerous enlarged lymph-glands. The normal appearance of the common bile-duct formed a sharp contrast to the duodenum. The last portions of the pancreatic and common bile-ducts were laid open. These also were of normal appearances, except the termination in the ampulla of Vater, which was swollen, congested, and blue.

In Case 9 a probe passed along the common duct (before the latter was opened) into the duodenum dislodged a formed plug which was impacted in the ampulla. A film made from this plug showed numerous epithelial cell nuclei embedded in a matrix of mucin. The structure of the ampulla with the plicated arrangement of the mucous membrane within its lumen favours such impaction and obstruction, as Fig. 3 shows. That an inflammation of the duodenum exists is further borne out by the results of duodenal intubation. On numerous occasions the withdrawn duodenal contents showed the presence of polymorphonuclear leucocytes and large mononuclear cells, which were obviously the result of local inflammation.

It would seem to be clear, therefore, that in some instances the spirochætal infection localises in the duodenum.

The liver in each of Cases 7, 8, and 9 showed to the naked eye only insignificant or slight changes. It was nearly normal in size; its cut section was of a greenish hue and firm in texture. In each the gall-bladder was normal in size and appearance.

On microscopic examination the liver cells in Cases 7 and 8 were natural in appearance and arrangement, the lobules were clearly defined, and, apart from biliary stasis, the only abnormal feature was collections of cells in the portal areas, such as occur in many diseases. (Figs. 4, A and B.)

Case 9 shows slight though definite changes in the liver. There is some loss of lobular pattern; the hepatic cells here and there show undue variation in size and shape, or their nuclei are large or multiple; a few mitotic figures are to be seen in the cells, and vacuolation of the cytoplasm can be observed. (Fig. 5.) In scrapings from the liver one definite spirochæte was seen.

In contrast to the foregoing there are cases in which the duodenum shows no notable change, and the liver, though not presenting any marked morbid appearance to the naked eye, shows definite changes on microscopic section. In Fig. 6 the liver cells are dissociated, many are markedly enlarged, with well-stained nuclei. Other cells contain two nuclei, and mitoses are numerous. In the centres of the lobules the cells are less well defined, stain imperfectly, and show slight granular changes. These changes suggest the effect of damage which has been insufficient to produce extensive necrosis, but has acted as a stimulus to cell growth. They somewhat resemble what is seen in subacute yellow atrophy

The next example came from an acute case of only a few days' course. It shows a liver that is the seat of advanced changes, both naked-eye and microscopic. It is diminished in size, its capsule is wrinkled, and in section there are loss of lobular pattern and numerous yellow areas of necrosis. Here complete destruction of liver cells may be seen, the framework of interstitial tissue only being left. Elsewhere in the section groups of hepatic cells show evidence of reaction—double nuclei and mitotic figures. Some large mononuclear cells are seen loaded with bile-pigment, and there is polymorphonuclear infiltration. The endothelial lining of the bile-capillaries seems to be healthy. (Fig. 7.)

Hart describes his own observations with those of Pick and other German workers. He bears out the earlier observations in the British Army, that the disease falls with varying force on the liver, the changes showing gradations between the slightest deviation from normal structure and an extreme disorganisation indistinguishable from acute yellow atrophy.

He further quotes an autopsy of a case which lived three months, illustrating the later anatomical changes following disorganisation of the liver. This liver had an irregular surface, lobular structure was lost, only islands of liver-

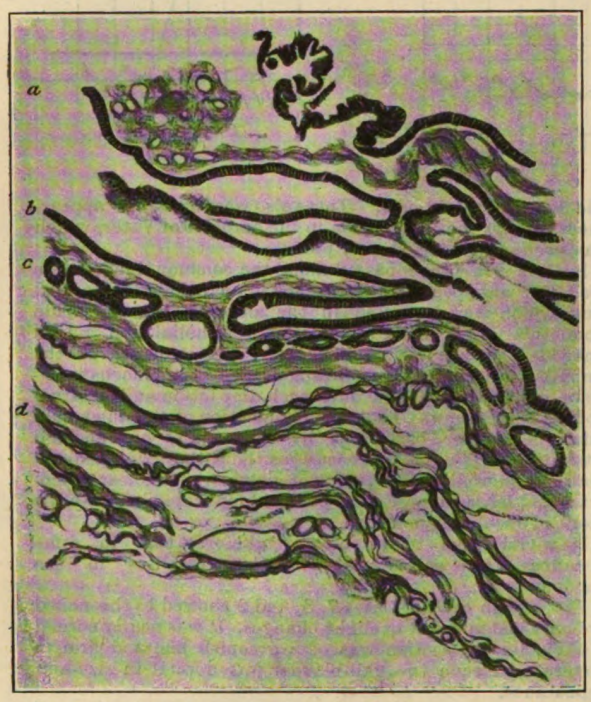


FIG. 3.—Section of ampulla of Vater. *a*, folds within lumen of ampulla; *b*, mucous membrane of ampulla; *c*, crypts; *d*, submucous coat.

tissue remained, and there was an extensive fibro-nuclear infiltration round these islands—in other words, anatomically cirrhosis had supervened on acute yellow atrophy.

Other organs.—The changes in the kidneys likewise vary, though not to the same extent as those in the liver. In one case the appearances are merely those of cloudy swelling; in another there is inter- and intra-tubular infiltration with polymorphonuclear leucocytes (Fig. 8); while in another (Fig. 9) there are, in addition, hæmorrhages in the glomeruli causing disruption of cells; the protoplasm of the tubular cells stains badly, has a granular appearance, and shows vacuolation—in short, the process approaches necrosis.

The spleen and pancreas show no departure from the normal, but peritoneal, sub-pleural and sub-pericardial hæmorrhages are common. Hæmorrhages are found in the substance of the lung, and in some instances reach the size and consistency of those met with in mitral stenosis.

PRESENCE OR ABSENCE OF JAUNDICE.

It is clear, therefore, that whether judged from clinical manifestations or pathological appearances not always the same organs receive the brunt of this infection, a fact with which we are familiar in other diseases, notably another spirochætal infection—viz., syphilis. The duodenum and

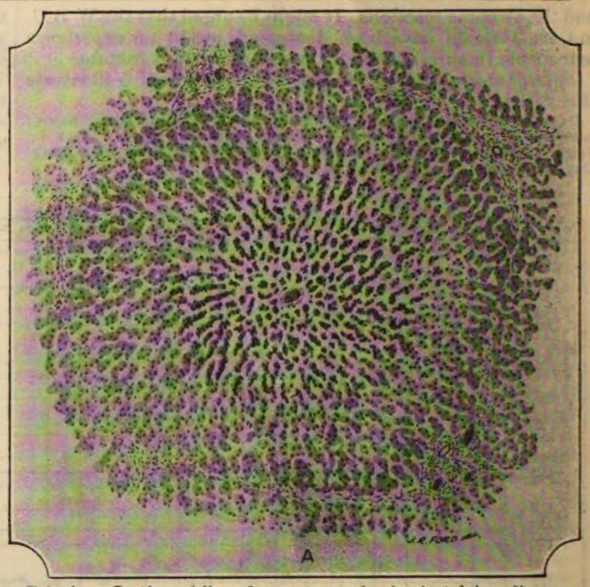

FIG. 4 A.—Section of liver from a case of spirochætal jaundice.

the liver are frequently selected, and as a result jaundice is a common feature.

What then is the immediate cause of the presence or absence of jaundice? Where there are inflammation and swelling of the duodenum and the papilla of Vater and no changes within the liver except bile stasis it is caused by obstruction of the outlet of the common duct. Where there is disorganisation of the lobules, with damage to the cells and intrahepatic ducts, the jaundice is caused by interference with the drainage of the bile within the liver. Where there are no definite changes in the liver and no swelling of the duodenum, jaundice is absent. Repeated examinations of blood have been made to make sure that the jaundice was not due to over-production of bile, but there has never been any evidence of blood destruction, and in two cases in which it was tested the blood fragility was normal in one and decreased in the other.

A comparison between acute yellow atrophy and spirochætosis icterohæmorrhagica is worthy of attention. On the pathological side two of the illustrations I have shown manifest a striking resemblance to acute and subacute yellow atrophy. On the clinical side acute yellow atrophy,

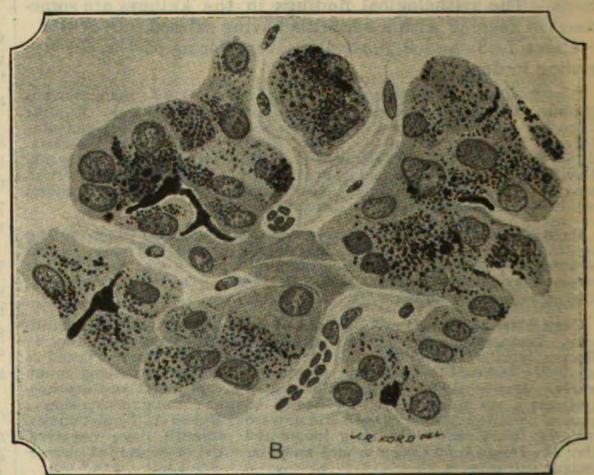

FIG. 4 B.—Part of the same section more highly magnified. The liver cells and their arrangement appear normal. Biliary stasis is evident.

though usually running a rapid course, may extend to 14 or more days' illness. Again, in the wards the clinical picture has often been that of acute yellow atrophy, and yet there have been no characteristic changes in the liver after death, and we get out of the difficulty by calling these cases "icterus gravis." Further, Rolleston records the following case of acute yellow atrophy without jaundice.

Onset sudden, with pain and slight hæmatemesis. On second and third days hæmatemesis, and on following three days melæna. On second day liver dullness was diminished. The temperature was usually between 99° and 100° F. No jaundice. The patient became progressively weaker and drowsy, and died on the eighteenth day. Post mortem the liver showed acute yellow atrophy.

I do not suggest that acute yellow atrophy as we have known it is due to this spirochæte; rather, that what we style in the post-mortem room acute yellow atrophy is the fullest anatomical expression of a destructive process of which there are several grades, and which may be caused by several agencies, *Spirochæta icterohæmorrhagiæ* amongst them.

THE DISEASE IN THE GUINEA-PIG.

Now we will deflect for a moment to the disease in the guinea-pig in so far as it bears on the human problem. The guinea-pig, the mouse, the rat, and the rabbit are all prone to the disease, and of these the guinea-pig is the most susceptible. In the guinea-pig the disease incubates for 6 to 13 days; its manifestations comprise fever (103° F. or higher), conjunctival congestion, hæmorrhages, jaundice, and albuminuria. The jaundice appears when the temperature has reached its maximum, the animal then becomes more acutely ill, and 24 hours after its appearance there is a fall of temperature to subnormal, followed by collapse and

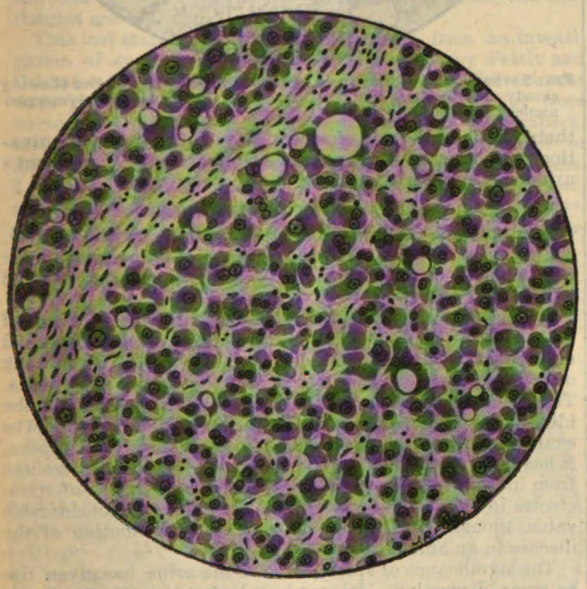

FIG. 5.—Section of liver from Case 9 showing slight changes.

death. Spirochætes appear in the blood with the onset of fever, and appear in the urine soon afterwards. The jaundice is usually deep, though in some cases it is faint, and occasionally absent.

The pathological changes in the guinea-pig are very characteristic. The skin and internal surfaces are coloured yellow, hæmorrhages are widespread in the skin, alveolar tissues, muscles, under serous membranes, and in the post-peritoneal tissues in the region of the kidneys. The lymph glands are enlarged and frequently hæmorrhagic. The small bowel is usually congested and may show numerous hæmorrhages under its serous coat. In some instances the mucous membrane of the duodenum has been more congested and swollen than that of the rest of the bowel. Hæmorrhages occur prior to the jaundice. The liver to the naked eye appears natural. Microscopically the changes vary from cloudy swelling to acute parenchymatous degeneration, small areas of necrosis being found in the section. The kidneys are acutely congested and show minute hæmorrhages subcapsular and throughout the cortex. Microscopically the changes are those of parenchymatous nephritis. The tubular epithelium often shows degenerative changes, and there is a leucocytic infiltration around and in the tubules. The suprarenals are usually hæmorrhagic, as is prone to be the case in any toxæmia in the guinea-pig. On the surfaces of the lungs are hæmorrhages so arranged as to give the lungs the appearance of "the wings of a mottled butterfly." The heart shows nothing, except that it may be the site of small hæmorrhages.

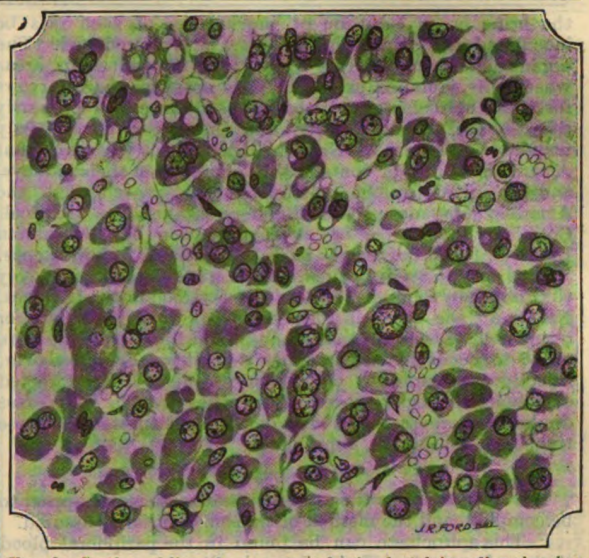

FIG. 6.—Section of liver from a case of spirochætal jaundice showing dissociation of cells and marked degenerative changes.

Whereas the spirochæte is found with difficulty in man, it is abundantly present in the guinea-pig. It is found with ease in the blood of the jaundiced animal and in its liver; a smear from the latter will show a dozen or more spirochætes per oil immersion field. In the kidneys and suprarenals the spirochætes are also plentiful, though patchy in their distribution. They are numerous in the urine from the onset of the jaundice. The spirochætes are excreted in the urine, fæces, and bile, all three of which are infective for the guinea-pig (and would be for man), and especially the bile, notwithstanding the fact that the Japanese workers have failed to demonstrate the spirochæte in the bile.

The disease is best conveyed to the guinea-pig by the intraperitoneal injection of 3 to 5 c.cm. of blood, either from an infected guinea-pig or human, though in the case of the latter the infectivity is limited to the first few days of the illness. As regards the infectivity of the urine there is difference of opinion. The Japanese workers found the

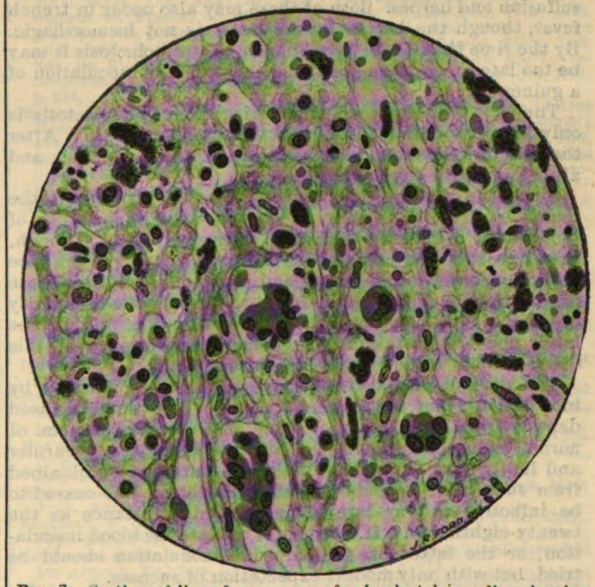

FIG. 7.—Section of liver from a case of spirochætal jaundice showing extreme degrees of change.

patient's urine infectious for guinea-pigs, and so did the French, whereas Stokes and ourselves failed in a limited number of efforts to convey the disease in this manner.

SOURCE OF INFECTION IN MAN.

By what means do human beings become infected? As was first pointed out by the Japanese workers, this spirochæte is found in the kidneys and urine of rats. If either

the urine or an emulsion of the kidneys of such rats be inoculated into guinea-pigs the disease is reproduced. The organism is found in rats away from, as well as in, areas where this jaundice prevails. Rats act, then, as reservoirs for these spirochætes. Probably the disease was primarily rife amongst these rodents, and the latter have slowly acquired tolerance. Noguchi has recently shown that American wild rats contain this organism in their kidneys, and by immunisation experiments has proved that the American, Japanese, and Flanders strains are identical. Coles, in the course of an investigation on 100 rats in England, found *Spirochæta icterohæmorrhagiæ* in 9 instances.

It is easy to see how the infected urine of rats can convey the disease by fouling the water and the food in the trenches. Nearly all the cases in Flanders occur in men who are, or recently have been, in the trenches, and the disease is more prone to occur in wet trenches than dry ones. Moreover, infection appeared to be endemic; thus, if an infected detachment was removed from the trench the cases diminished, whereas if a new detachment entered the same trench cases began to appear in it.

DIAGNOSIS.

The evidence as to the cause of this disease would appear to be complete and the method of transmission fairly assured.

1. This spirochæte can be found in the peripheral blood stream of patients suffering from the disease.
2. Injection of infected human blood into the peritoneal cavity of the guinea-pig will produce a characteristic fatal illness in that animal, in whose tissues the spirochætes are present in large numbers.
3. The spirochæte has been isolated in pure culture, and inoculated from such culture the guinea-pig contracts the disease.
4. The disease has been produced in man by accidental inoculation from an infected guinea-pig.
5. After the first fortnight of the disease the spirochæte may be found in the patient's urine, and in the third week of the disease the patient's serum agglutinates the spirochæte.

The difficulty in diagnosis lies in the fact that in the early stages the symptoms may only be those common to several diseases. Enteric fever, trench fever, influenza, and other fevers may show the same initial symptoms. The occurrence of hæmorrhages would certainly suggest spirochætosis; the same would be true, though in less degree, of conjunctival suffusion and herpes. Both of these may also occur in trench fever, though the herpes in the latter is not hæmorrhagic. By the time that there is suspicion of spirochætosis it may be too late to ensure a positive result from the inoculation of a guinea-pig.

The blood of the patient suffering from spirochætosis is only infective during the early stages of the disease. After the fifth day the chances of a positive result diminish, and after the eighth day are few.

Since the average day of appearance of jaundice is the fourth or fifth, it is easy to see that the opportunity of inoculating a guinea-pig in time may easily slip. Though, therefore, this diagnostic test is conclusive, it has in practice its limitations. In mild cases and non-jaundiced cases these limitations are even greater, for in the former the infectivity of the patient's blood is of more brief duration, and in the latter the manifestations suggesting the presence of this disease would often be too late in appearing.

The disease may also be conveyed to the guinea-pig by inoculation from the patient's urine. The centrifugalised deposit from 40–60 c.cm. of urine suspended in 5 c.cm. of normal saline solution is the injection employed. Garnier and Reilly have shown that positive results may be obtained from such urine inoculations after the blood has ceased to be infective and as late in one recorded instance as the twenty-eighth day. If, then, it is too late for blood inoculation, or the latter has failed, urine inoculation should be tried, but with only modest expectation of success.

Direct examination of the blood is of small value because the spirochætes are only present in the circulation during the first days of the disease, and then only in scanty numbers. The organisms are, however, sometimes found, and smears stained by Fontana, Giemsa, or Leishman are worth making.

In practice if the guinea-pig inoculated with the patient's blood is negative and the inoculation were not done early enough to justify the acceptance of a negative diagnosis there has to be a delay of several days before other examinations can be fruitful. These are examinations of the patient's urine and agglutination tests.

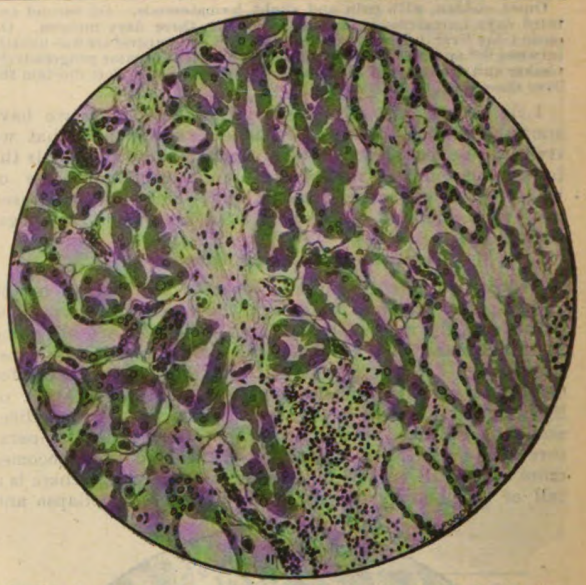

FIG. 8.—Section of kidney from a case of spirochætal jaundice showing cloudy swelling as well as inter- and intra-tubular polymorphonuclear infiltration.

SPIROCHÆTES IN THE URINE.

The spirochætes are eliminated chiefly by the kidney. They appear in the urine about the ninth day, reach their maximum about the fifteenth day, and disappear at the end of the fifth week.

Collect the urine in a sterile vessel, centrifuge 50 c.cm. of it, wash the deposit with sterile water, re-centrifuge and make smears with the final deposit, stain by the Indian ink or collargol method, or better still by the method of Fontana. This method needs practice both in its technique and in the identification of the typical spirochæte. The urine should be examined on two or three occasions. If, as often happens, it has been too late either to perform or to draw inferences from inoculation of a guinea-pig, the demonstration of spirochætes in the urine at a later stage is evidence of considerable value, though less convincing than the reproduction of the disease in an animal.

The significance of spirochætes in the urine has given rise to some discussion. It may be asked, Are not spirochætes found in the urine in other conditions besides this disease? Can the specific spirochæte be morphologically distinguished from other spirochætes?

It is known that spirochætes are found in the urethra and about the meatus. These can be excluded by adopting precautions in the collection of the urine. Stoddard examined 50 patients who had no recent history of a relapsing fever and 50 healthy soldiers. He made smears of the material taken from the meatus and distal urethra. He found spirochætes in 50 per cent. of the former series and in 22 per cent. of the latter series. It is admitted that spirochætes are found in the urethra and round the meatus, though other observers do not find them with the frequency of Stoddard's figures. These spirochætes are thick, have a varying number of regular coils, and do not show morphological resemblance to the spirochæte of this disease.

In examining control urines (collected with the usual precautions) from cases of scarlet fever, measles, lobar pneumonia, enteric fever, &c., Bedson, in my laboratory, only rarely found this thick spirochæte with the regular coils which belongs to the meatus and adjacent urethra.

This observation is confirmed by J. A. Wilson, who, while microscopically examining catheter specimens of urine from 90 cases of albuminuria, only found spirochætes in 6 cases, and these were of the urethral type. It must be admitted, however, that these 90 cases were afebrile.

It is also confirmed by Flessinger, who in view of Stoddard's observations undertook the examination of 93 men: 45 were well and 48 ill. Of the 45 who were well, in only 4 of them were spirochætes obtained in urethral or

meatal smears and in only 1 of the urines. Of the 48 who were ill spirochætes, which were neither meatal nor "icterohæmorrhagica," were found in 3.

On the other hand, Patterson, on examining urines (collected with precautions) of a small series of febrile cases (P.U.O.),* found spirochætes often abundantly during and immediately after the rise of the temperature and scantily during the afebrile intervals. Though one of his illustrations depicts the urethral type of spirochæte, his observation receives some support from Nankivell and Sundell, who found spirochætes, not of the urethral type, in the urines of 12 out of 15 trench fever cases examined.

Weighing up these observations we may conclude: (1) that there exist contaminating urethral spirochætes of the meatal type and the *refringens* type, with characteristic features which may be eliminated as a source of error by washing the glans and meatus and catching the middle portion of urine in a sterile flask; (2) that in healthy and most ill people spirochætes are not excreted by the kidney; (3) that in spirochætosis icterohæmorrhagica the causal spirochætes are always excreted by the kidney; (4) that, as shown by Patterson and Flessinger in some cases of fever of unknown origin (P.U.O.) (but excluding enteric), spirochætes other than those of spirochætosis icterohæmorrhagica are excreted.

This last statement receives confirmation from an investigation of an outbreak of P.U.O. at Lorient by Pettit and Cristan. Their findings were as follows: 1. Spirochætes were present in the urine of these patients. They were numerous and found in greatest numbers when the temperature was high, and they were observed, unlike those of spirochætal jaundice, from the commencement of the illness. 2. This spirochæte, called *S. Lorient*, is longer and thicker, and its curves more irregular and deeper than *S. icterohæmorrhagiæ*, but the differences are not very marked. 3. Guinea-

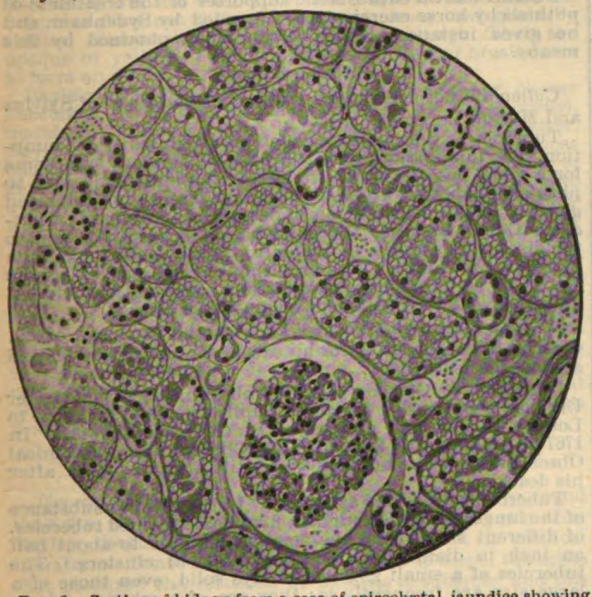

FIG. 9.—Section of kidney from a case of spirochætal jaundice showing marked degenerative changes in the parenchyma.

pigs possess complete immunity from *S. Lorient*. 4. The serum from patients convalescent from *S. Lorient* does not protect the guinea-pig from *S. icterohæmorrhagiæ*.

The epidemic at Lorient was very contagious. Jaundice was comparatively rare (5 per cent.); rheumatic pains were a common feature; sometimes the spirochæte was not found in the urine.

There is, then, another pathogenic spirochæte whose appearances are somewhat close to those of *S. icterohæmorrhagiæ*, and this fact has to be borne in mind. But in the diagnosis of spirochætosis icterohæmorrhagica the presence of the typical spirochæte taken in conjunction with the clinical manifestations is strong evidence on which a positive conclusion is warranted.

Before concluding I should like to take this opportunity of heartily thanking my colleague Captain S. P. Bedson, R.A.M.C., for his valuable help in the work of this address.

* Pyrexia of uncertain origin.

The Harveian Oration
ON
THE DOCTRINE OF CONSUMPTION IN HARVEY'S TIME AND TO-DAY.

Delivered before the Royal College of Physicians of London on Oct. 18th, 1918,

BY PERCY KIDD, M.D.OXON., F.R.C.P. LOND.,
PHYSICIAN, LONDON HOSPITAL; CONSULTING PHYSICIAN, HOSPITAL FOR CONSUMPTION AND DISEASES OF CHEST, BROMPTON, ETC.

(*Concluded from p. 546.*)

OBSERVATIONS OF OTHER AUTHORS.

Thomas Willis (1621–1678) deals very briefly with the subject, but he makes the important observation that the general belief that phthisis is a pining away of the whole body arising from an ulcer in the lung is untrue. In proof of this statement he says that he had opened the dead bodies of men who had died of this disease, in whom the lungs were free from any ulcer, and yet they were set about with tubercles or stones or sandy matter throughout.

"Wherefore phthisis is better defined as a withering away of the whole body arising from an ill formation of the lungs."

Waldenburg thinks that Willis may have intended to describe miliary tubercles by the term "sandy material."

Sydenham (1624–1689) added nothing fresh to our knowledge of consumption, but he recommended daily riding on horseback as the principal assistant in the cure of this disease.

Bonetus, a contemporary of Sylvius and Willis, in his "Sepulchretum," gives records of 150 necropsies of consumption from his own experience and from that of others. He regards phthisis as due to many different causes: ulcer of the lung, abscesses, scirrhous tumours, tubercles, vomicæ. He speaks of tubercles as tubercula glandulosa, following Sylvius. Vomicæ are closed collections of pus which resemble ordinary abscesses, but may be formed from tubercles. He seems to have described miliary tubercles in the following passage:—

"Pulmonum parenchyma ..... duriusculum erat et multis quasi granulis instar steatomatum quae aliquid sebacei continebant, refertum."

Mangetus, who edited the "Sepulchretum" of Bonetus in 1700, added some further cases of phthisis, among which are included instances of generalised miliary tuberculosis. One case is summed up thus: "Grandines pulmonum aliorumque partium cum phthisi."

Morgagni (1682–1771) was so convinced of the contagious nature of consumption that he carefully avoided the dissection of those dead of this complaint. The cases which he describes in his great work, "De Sedibus et Causis Morborum," seem to have been drawn from the records of his teacher, Valsalva, who held similar views about contagion. Valsalva made the important observation that in all the cases he had dissected the ulcers and disease were in the upper part of the lungs. Morgagni considered that phthisis may be the result of the suppuration of tubercles, but he recognised other causes, and he accepted Morton's opinion concerning the connexion between scrofula and consumption.

Pierre Desault.

Pierre Desault, a physician of Bordeaux, who lived in the latter part of the seventeenth and the early part of the eighteenth century, published his views on phthisis in 1733, four years before his death.

In this work, which has great merit, he expresses himself very clearly. The causes of phthisis are divided into conjoint and antecedents. The conjoint cause is that whose presence sets up the disease and whose destruction leads to a cure. This cause he refers to tubercles and concretions found in the substance of the lung and scattered through the different lobes. These concretions resemble hailstones and are of different sizes. From this description it is probable that Desault was acquainted with miliary tubercles. He goes on to say that—

"If we read Morton's book on phthisis we shall find no account of an autopsy without the discovery of tubercles, to which he ascribes all the symptoms of the disease in such a fashion that I need do little more than translate and copy his words."

All previous writers, both ancient and modern, with the exception of Willis, were agreed that the cause of phthisis is an ulcer of the lung. Desault rejects this view, relying on the results of his own experience. Post-mortem examination of certain cases of phthisis which presented characteristic symptoms during life revealed a complete absence of ulceration, though the lungs were stuffed with tubercles. Phthisis is due to tubercles; ulceration of the lung is a secondary process. The symptoms of the disease precede the occurrence of ulceration, and are therefore not due to ulceration but to tubercles.

He compares phthisis with scrofula (*écrouelles*), both of them chronic diseases. Phthisis begins with tubercles or tumours in the lung, scrofula with tumours in the neck. In both cases the tubercles or tumours become inflamed and suppurate. Suppuration of scrofulous tumours leads to the formation of ulcers which are slow to heal, and can only be cured by destroying the tumours and the cause which produces them. The same is true of ulcers in the lungs resulting from the suppuration of tubercles. Both diseases in the stage of suppuration are contagious.

Desault believed that the contagion in this case, as in venereal disease, depends on the presence of worms. If we substitute micro-organisms for worms, there would be little to add even now to this statement, and, in any case, we may fairly credit Desault with a true prophetic instinct. The doctrine of "phthisis ab hæmoptoe" advocated by Morton and nearly all previous authors is rejected by Desault, who says that this chapter in Morton's book should be headed "Hæmoptoe a Phthisi," for hæmorrhage is the result, not the cause, of phthisis.

Young people between the age of 18 and 35 are most liable to be attacked by phthisis, as Hippocrates pointed out, but other ages are by no means exempt, for one meets with the disease in persons at ages below and above these limits, though less frequently. The subjects of phthisis for the most part are: 1. Those with contracted alar chests. 2. Those with a phthisical parentage and hereditary disposition. 3. Those exposed to contagion, in which Desault is a firm believer.

"Those who live with phthisical patients and wait on them may take the disease, though there be no hereditary disposition, for it is contagious. Thus wives who wait upon their phthisical husbands often contract the disease, and husbands who wait on their phthisical wives."

Desault was an enthusiastic supporter of the treatment of phthisis by horse exercise recommended by Sydenham, and he gives instances of the good results obtained by this means.

Cullen and Stark.

Cullen did not make much advance on the views of Sylvius and Morton.

Tubercle is the commonest of many causes of consumption. The lung may contain tubercles without any symptoms for a time, but finally the tubercles suppurate and lead to phthisis. Tubercles are small swellings resembling indurated glands. Phthisis is common in persons of scrofulous parentage. Cullen assumes the existence of a predisposition to the disease in certain individuals. Some cases that cough up calcareous matter, with or without blood, recover, others die. Asthma frequently terminates in consumption. Cullen did not favour the contagious origin of the disease.

William Stark, who died in 1770 at the early age of 29, deserves special mention for his excellent work on the morbid anatomy of phthisis.

Educated at Glasgow and Edinburgh, at which latter University he was a favourite pupil of Cullen, he came to London in 1765 and entered at St. George's Hospital. In 1767 he graduated at Leyden. His Clinical and Anatomical Observations were not published till 1788, 18 years after his death.

Tubercle is described as follows. In the cellular substance of the lungs are found roundish firm bodies named tubercles, of different sizes, from the smallest granule to about half an inch in diameter; the latter often in clusters. The tubercles of a small size are always solid, even those of a large size are frequently so; they are of a whitish colour, and of a consistence approaching nearly to the hardness of cartilage; when cut through the surface appears smooth, shining, and uniform. No vesicles, cells, or vessels are to be seen in them, even when examined with a microscope, after injecting the pulmonary artery and vein.

This description shows that he was familiar with miliary tubercles, though he does not use that term. He then traces the development of vomicæ from tubercles and their communication with the air passages. Near the larger cavities the pulmonary vessels are suddenly contracted and the bronchi are thickened. The upper and posterior parts of the lung are first and most affected. Stark gives what I believe is the first account of an aneurysm of the pulmonary artery, measuring 1 × ½ inch, opening into a vomica in the lung with a slit on one side of it. The patient died of hæmoptysis. No explanation of the cause of the aneurysm is offered.

Matthew Baillie's Description of Tubercles.

Matthew Baillie (1761–1823) at the end of the eighteenth century gave an admirable description of tubercles in the lungs, to which little has been subsequently added.

He believed that tubercles arise in the cellular tissue of the lungs and are not glandular in origin, as no glands exist in the lungs, "and on the inside of branches of the trachea, when there are follicles, tubercles have never been seen."

Tubercles "are at first very small, being not larger than the heads of very small pins, and in this case are frequently accumulated in small clusters. The smaller tubercles of a cluster probably grow together and form one larger tubercle. The most ordinary size of tubercles is about that of a garden pea, but they are subject in this respect to much variety. They adhere closely to the substance of the lungs, have no peculiar covering or capsule, and have little or no vascularity. When cut into they are found to consist of a white smooth substance possessing a firm texture, and they often contain in parts a thick curdy pus.

In cutting into the substance of the lungs a number of abscesses is sometimes found, from tubercles of a considerable size having advanced to a state of suppuration. In the interatices between these tubercles the lungs are frequently of a solid texture, from the cells being in a great measure obliterated. The texture of the lungs on many occasions, however, round the boundaries of an abscess is perfectly natural. ..... When tubercles are converted into abscesses phthisis pulmonalis is produced, one of the most destructive diseases in this island."

In other parts the lung may be converted into a white soft material, like that of a scrofulous gland just beginning to suppurate. This appearance he attributes to scrofulous matter deposited in the lungs.

"It seems to be the same matter with that of the tubercle, but only diffused uniformly over a considerable portion of the lungs, while the tubercle is circumscribed."

Baillie described tubercles in other organs, but he did not offer any explanation concerning their relation to similar disease of the lung.

The Influence of Bayle's Views.

The great work of Bayle in the early part of the last century marks the commencement of a new era in the conception of phthisis.

He divided the disease into several classes—tuberculous, granular, ulcerative, melanotic, calculous and cancerous; of these the tuberculous is the most common. This artificial classification, including tuberculous and non-tuberculous affections, did not long survive. Bayle's description of tubercles does not differ in essentials from that given by Baillie. The smallest tubercles he calls miliary. These are opaque or yellowish and tend to suppurate and break down to form an ulcer.

Bayle's criterion of tubercle was an opaque or cheesy substance. Tubercle may be encysted or non-encysted, nodular or diffused. What Baillie called scrofulous matter, Bayle called tuberculous. Like Baillie, he assumed a close connexion between scrofula and tubercle. In addition to tubercles, certain transparent hard miliary nodules were described in the lungs; these were called miliary granulations and were stated to differ from miliary tubercles in the fact that they never became opaque or cheesy. From their hardness and translucency, Bayle regarded them as of the nature of cartilage.

The simultaneous appearance of tubercles in various organs of the body convinced Bayle that the explanation was to be found in a common cause and he attributed this dissemination to a tendency to the production of tubercles, a tuberculous diathesis or disposition. This diathesis was the common cause of tuberculous phthisis, which is a general disease, and for this condition the term tuberculosis was first employed by Bayle.

LAENNEC'S DOCTRINE OF THE UNITY OF PHTHISIS (1781–1826).

The conception of a tuberculous diathesis had a profound influence on contemporary thought, and for 50 years after Bayle's death its effects could still be traced in medical literature. It needed the touch of genius to dispel the mists that obscured the relations of phthisis to tubercle, and this was supplied by Laennec's masterly treatment of the whole subject. Laennec proclaimed the doctrine of the unity of phthisis. All phthisis is tuberculous.

"Tuberculous matter may be developed in the lungs and other organs under two principal forms: that of isolated bodies and that of infiltrations. Whatever be the form under which the tuberculous matter is developed it presents at first the appearance of a grey and semi-transparent substance, which becomes by degrees yellow, opaque, and very dense. It then softens, gradually acquires a liquidity about equal to that of pus, and being expelled through the bronchi it leaves in its place cavities commonly known as ulcers of the lung, and which I shall designate by the name of tuberculous excavations."

He then describes miliary tubercles and Bayle's granulations and shows that transitional forms connect the two, proving that the latter are only an early stage of the former; in his own words—

"There is no other difference between them than that which exists between the green fruit and the ripe."

All cheesy matter is tuberculous, even that which is sometimes seen in cancerous growths. Inflammation plays no part in the production of tubercles which may develop in any organ of the body and are to be regarded as new formations.

Scrofulous glands are tuberculous. Hæmoptysis is never the cause of phthisis, but is always the result of disease already established. Tubercle, wherever situated, is connected with a certain disposition, but "the real cause, like that of all diseases, is probably out of our reach."

These views met with strong opposition on the part of some of Laennec's own countrymen.

Thus Broussais, accepting the tuberculous nature of phthisis, regarded tubercle as the result of irritation and inflammation of the lung, pleura, or bronchi, reverting to the standpoint of the seventeenth century, when the Hippocratic tradition still largely prevailed.

Andral took up a somewhat different position. While he embraced the idea of a tuberculous diathesis, he denied that tubercle is a new formation. According to his conception caseous or tuberculous material represented inspissated secretion in the small bronchi and lung which gradually becomes more compact and ultimately suppurates. The common causes of phthisis are pneumonia, pleurisy, catarrh, or hæmoptysis occurring in persons with a tuberculous diathesis. He supported Bayle's view that miliary granulations are distinct from miliary tubercles and considered that they represented discrete areas of alveolar inflammation.

Louis by his elaborate pathological and clinical observations gave strong support to Laennec's views.

Rokitansky put forward a theory of a tuberculous crasis, dyscrasia or blood change depending on a hyperinosis. Tubercle is an exudation which may be inflammatory and acquires a special fibrinous or tuberculous character in virtue of a tuberculous crasis. Scrofula and tuberculosis are identical.

In England Laennec's doctrine in the main was generally adopted.

HISTOLOGICAL OBSERVATIONS.

Until nearly the middle of last century pathological views were based almost entirely on naked-eye observations. But about this time the microscope began to be employed with important results and numerous observations were made on the histology of tubercle.

Lebert described certain small cells or tubercle corpuscles which were pathognomonic of tuberculous material.

Reinhardt disputed the specificity of these cells and showed that similar appearances may be presented by pus corpuscles.

William Addison regarded tubercle as consisting of epithelial cells derived from the white corpuscles of the blood.

VIRCHOW'S WORK.

Virchow in his great work "Die Krankhaften Geschwülste" essayed to revolutionise the whole doctrine of tuberculosis.

Miliary tubercle is the only criterion of what is tuberculous. Caseation, though a common change in tubercles, is not a specific process; it may occur in new growths, and is often the result of inspissated pus. This transformation is a necrobiosis and is allied to other forms of degeneration. In pulmonary phthisis inflammation is the chief factor and may terminate in caseation. Tubercle plays a subordinate part. The cells of tubercle resemble the cells of a lymphatic gland. Tubercle is a heteroplastic lymphoma; its seat is the connective tissues of the body.

Scrofula is not a specific disease, but a manifestation of a general vulnerability of tissue and proclivity to disease. Heredity is recognised as a potent factor. What is inherited is a certain disposition or vulnerability, not the disease itself.

Niemayer applied Virchow's views in their most extreme form to the clinical history of phthisis, which he divided into two groups—miliary tuberculosis and chronic caseous pneumonia.

Any form of pneumonia may terminate in phthisis, but in most cases it is a chronic catarrhal pneumonia which leads to caseation and excavation. Hæmoptysis may set up a caseating pneumonia and is a common cause of phthisis. Miliary tuberculosis is seldom a primary affection of the lung, but is generally secondary to ulcerative pneumonia or to a caseous lymphatic gland. Phthisis is not a specific disease and is not hereditary. A congenital vulnerability and a tendency to a luxuriant growth of cells are the distinguishing marks of this disease, and in this sense there is a connexion between phthisis and scrofula.

This profession of faith, supported by the great authority of Virchow, found much favour in Germany. But in France and England the great majority of physicians held firmly to Laennec's doctrine of the unity of phthisis.

DEMONSTRATION OF INFECTIOUS NATURE OF TUBERCULOSIS.

In 1857, when discussions about tubercle were still chiefly concerned with histological details, Buhl came forward with

the important statement that generalised miliary tuberculosis is the expression of an infection of the blood originating in a caseous focus situated in a lymphatic gland, in the lung or in some other part of the body. This was the first attempt to explain tuberculosis on the basis of infection and constitutes a landmark in the inquiry.

Seven years later Villemin made known the results of his memorable researches on the experimental production of tuberculosis in animals.

Rabbits and guinea-pigs inoculated with miliary tubercle, caseous matter or phthisical sputum, invariably developed tuberculous lesions in the serous membranes, lungs, and other organs. In certain animals, such as dogs, cats, and sheep inoculation was unsuccessful. Control inoculations with other material, such as cancer or anthrax, invariably failed to produce tuberculosis.

Villemin concluded from his experiments that tuberculosis is a specific inoculable disease, and he compared it with virulent maladies like small-pox, syphilis, and glanders. These conclusions were disputed at first on the ground that tuberculous lesions could be produced experimentally by the injection of non-tuberculous material. But after much controversy the truth of Villemin's views was universally acknowledged.

Discovery of the Tubercle Bacillus.

In 1867 William Budd, basing his opinion on geographical and epidemiological considerations, enunciated the view that phthisis is a zymotic disease like typhoid fever and that its propagation is determined by infection. But all doubts as to the infective nature of tuberculosis were removed by Koch's famous announcement in 1882 of his discovery of the tubercle bacillus.

The facts concerning Koch's brilliant research and the overwhelming proofs adduced by him in support of his conclusions are too well known to need recapitulation here. But we may pause a moment to pay homage to the genius of Laennec who conceived the doctrine of the unity of phthisis, to Villemin who supplied the first experimental evidence of the truth of this view, and to Koch who isolated the infective micro-organism, cultivated it outside the human body, and demonstrated its pathogenic action on the lower animals.

THE DOCTRINE OF CONSUMPTION AT THE PRESENT TIME.

Koch's discovery having furnished the most complete confirmation of Laennec's doctrine, non-tuberculous caseous pneumonia, which had long figured prominently in German writings, was now given a decent burial. Many elaborate and artificial classifications of phthisis shared the same fate. The old terms consumption and phthisis began to pass out of use, and tuberculosis, a term which we owe to Bayle, was generally adopted.

Heredity and Predisposition.

Some of Koch's most enthusiastic supporters were at first prepared to explain everything in the natural history of the disease by infection with the tubercle bacillus, and to throw all ideas of heredity and disposition to the winds. The temperate and judicial statements of Koch himself are in striking contrast with the attitude of these extremists, as Bulloch has pointed out.

In his monograph, "The Etiology of Tuberculosis," published in 1884, Koch admits that—

> "Although a good many of the phenomena classed together under the head of 'predisposition' may be referred to simple and easily explained conditions, some facts still remain difficult or impossible to interpret, compelling us for the present to accept the view of a varying liability."

He further agrees that tuberculosis is hereditary in the sense that a predisposition is inherited. Careful statistical investigations by Pearson supply strong confirmation of the existence of a hereditary disposition. This question has been very ably discussed by Bulloch and Greenwood, who concluded that—

> "the many workers who have dealt with the problem of inheritance and infection during the last few years have failed to achieve any real solid advance from the classical position."

Human and Bovine Tuberculosis.

In Koch's opinion the main, if not the only, source of pulmonary tuberculosis is the dried sputum of tuberculous patients which reaches the lungs through the air passages. Villemin had expressed similar views. The aerogenic origin of the disease has been disputed, but the rival view which regards pulmonary tuberculosis as enterogenic has received less support than the former.

The relation of human to bovine tuberculosis had engaged the attention of Villemin, who concluded that the two diseases were different. But Klebs and later workers, including at first Koch himself, regarded them as identical. This was the prevailing view, though doubts were expressed by individual writers, until 1900, when Koch made the startling announcement that further experiments had convinced him that human and bovine tuberculosis are distinct diseases, and that pulmonary tuberculosis is invariably due to infection by bacilli of human origin.

In spite of numerous researches on the alleged morphological and cultural differences exhibited by tubercle bacilli of the human and bovine type, no general agreement has been reached. But that there is a difference in the pathogenic effects on animals there seems to be no doubt. Inoculation of bovine bacilli is followed by an acute general tuberculosis, whereas when human bacilli are employed the effects are limited to a local tuberculosis at the site of inoculation or to a comparatively mild and chronic form of infection. In 1903 Behring proclaimed the opinion that infection of infants by the milk of tuberculous cows is the chief source of pulmonary tuberculosis.

Further investigation, however, has confirmed the truth of Koch's view that pulmonary tuberculosis is invariably due to infection with tubercle bacilli of the human type. This question has been fully discussed by Bulloch in his Horace Dobell Lecture, delivered before the College in 1911, to which I am much indebted.

The Seed and the Soil.

Records of autopsies at hospitals show that in a large percentage of all dead bodies 70–90 per cent. arrested tuberculous lesions are found in the lungs or other organs. It is clear, therefore, that the number of persons that recover from the infection greatly exceeds the number of those that succumb. Man is evidently more resistant to tuberculosis than the ordinary laboratory animals, though less so than animals like the cat, dog, sheep, horse, and ass. Koch has pointed out that in the human subject a temporary immunity is often manifested, periods of partial or apparently complete recovery alternating with phases of active infection.

There seem, then, to be intermediate grades of immunity in man contrasting with the complete immunity of certain animals. By analogy we may infer that these different grades of immunity in man and the lower animals depend on defensive arrangements which are similar in kind and vary only in degree. We can hardly doubt that the explanation of these differences is to be found in biochemical variations at present imperfectly understood.

Hereditary disposition may be explained on similar lines. These considerations illustrate the importance of the part played by the soil in which the germ of tuberculosis is planted. This fact had not escaped the acute observation of Villemin, who insisted on the interdependence of two factors in tuberculosis, the virus and the "milieu organique."

A further study of the soil, or "milieu organique," is the most pressing need for the better understanding of the pathology of tuberculous infection. This inquiry is intimately connected with the explanation of immunity—a subject bristling with difficulties. In recent controversies as to the relative importance of phagocytosis and chemical action of the body fluids we seem to witness a renewal of the old contest between the cellular and humoral pathologists. But, in spite of the immense amount of research devoted to the study of immunity, no general conclusion has yet been reached. This need not surprise us in view of the complexity of the problems involved.

The Mortality of Tuberculosis at Various Age Periods.

When the infectious nature of the disease had been finally established by Koch great results were anticipated from the application of this knowledge to the prevention of tuberculosis. But, so far, the results have been disappointing.

The death-rate from phthisis had been steadily falling for a number of years before the discovery of the tubercle bacillus, and no accelerated reduction has taken place in recent years. Furthermore, since the Great War began in 1914 there has been a steady rise in the phthisis death-rate, the causes of which have yet to be worked out. A recent paper by Brownlee on the epidemiology of phthisis pulmonalis, based on statistical tables of the death-rates at different ages

in different districts, raises points of great interest. His conclusion is that there are at least two types of phthisis, one especially affecting young adults and one middle age.

The type affecting middle age seems to have been the chief type in London for more than 200 years. Sydenham's statement that the usual age at which death from phthisis occurs is between 15 and 30 is taken directly from Hippocrates. When Morton, who gives the actual ages of phthisis deaths, is consulted, it is found that a very large proportion of cases are over the age of 30. Further investigation has shown that the young adult type, which is the prevailing one in Ireland and Shetland, spreads independently of environment, being as common in the more healthy parts of a district as in the unhealthy, while the amount of middle-age phthisis is correlated to the unhealthiness of a district.

The explanation suggested is that phthisis is not one disease, but a mixture of at least two allied diseases, an explanation to which the recent discoveries regarding typhoid fever furnish an analogy. In one form of phthisis the chief death-rate occurs between the ages of 20 and 30 years; in a second form the maximum death-rate occurs between the ages of 45 and 50 years. This hypothesis does not, in the present form, explain the occurrence of phthisis at high ages observed in Wales and Cornwall. It is possible that the senile form is due to the same organisms as that which causes the young adult type. It is well known clinically that many persons develop phthisical lesions in their youth, which apparently heal, while later in life a recurrence of the disease or a new infection leads quickly to a fatal issue. No district by itself gave any clue to the meaning of the phenomenon of phthisis at the later age observed in Wales and Cornwall. Light on this type was obtained from the statistics showing the susceptibility to phthisis in different occupations. It was found from these data that a very marked susceptibility to phthisis at later ages was shown by coal-miners, though the total amount of phthisis occurring among them was very small.

A study of the phthisis death-rate in England generally during the last 60 years shows a great reduction at all ages. This is most marked at the age period 20 to 25 years. At the middle and later ages the fall has not been nearly so marked. The result has been to raise the mean age at which death from phthisis occurs. No completely satisfactory explanation of this fact is possible at present.

The figures available suggest that an epidemic of "young adult" phthisis culminated about the middle of last century, since which date that form of the disease has markedly diminished. It is to be hoped that further investigations on these lines will enable Brownlee to clear up some of the questions raised in his valuable paper.

CONCLUSIONS.

If we look back and review the progress of knowledge we see how Laennec's great generalisation was foreshadowed by the work of Richard Morton. For Morton was the first to point out that consumption is in all cases associated with the presence of tubercles in the lungs. Thomas Willis had previously broken away from the Hippocratic tradition that phthisis and ulceration of the lung are convertible terms.

Sylvius, their great contemporary, whose influence must have powerfully affected both Willis and Morton, had not taken up such a definite position himself, though, as already shown, he had made important contributions to the pathology of consumption. His views on the fluctuating activity of the humours or secretions of the body and their relation to consumption find their counterpart at the present time in the temporary immunity which Koch discerns in the course of many cases of tuberculosis. The mutual relations of the different humours or secretions advocated by Sylvius and the modern development of the doctrine of the endocrine glands provide another illustration of the well-known fact that no great discovery is made without some previous preparatory work. Again, though the conception of tuberculosis as an infection first took definite shape in consequence of the experimental work of Villemin, we know that a belief in the contagiousness of consumption can be traced back as far as the time of Galen and Aristotle. Let us not forget the debt we owe to the Ancients. "Vixere fortes ante Agamemnona multi."

How true was Elijah's outburst—"I am not better than my fathers."

ON A PYÆMIA DUE TO ORGANISMS OF THE *BACILLUS COLI* GROUP

OCCURRING IN TURKISH SOLDIERS.

BY J. I. ENRIGHT, M.B., B.CH. N.U.I.,
CAPTAIN, R.A.M.C.;
AND
P. H. BAHR, D.S.O., M.D. CAMB., M.R.C.P. LOND.,
CAPTAIN, R.A.M.C.

CASES of a peculiar pyæmia, with special involvement of the kidneys, apparently caused by *Bacillus coli* or one of its congeners, have been observed during the last year in Cairo. It was some time before the puzzling pyrexia with its attendant symptoms was recognised as a specific one. Nine cases in all were diagnosed in life, six others were recognised pathologically post mortem, but it is not improbable that the disease is much more frequent amongst debilitated orientals than these figures would indicate. In all but three of the cases which came to autopsy a dysenteric ulceration of the large intestine, and especially of the rectum, was present in all degrees of superficial necrosis and deep ulceration. Out of the six cases under treatment and still alive, three gave no history of a chronic diarrhœa or dysentery; the remainder had had many such attacks. It may be surmised that the organisms originally gained entrance to the blood stream through a breach of the mucosal surface in the lower part of the large intestine.

Symptoms, Clinical Signs, and Treatment, by Captain J. I. ENRIGHT.

Symptoms.—The onset of such a pyæmic attack is usually ushered in by severe frontal headache, anorexia, vomiting, and an acute pain localised to one or both kidney regions. This pain radiates along the inguinal canal and terminates in the penis, or may be localised to the scrotum. Blood is often passed in the urine in the initial stages. There is generally some difficulty in micturition, though there may be at the same time no frequency or alteration in amount of urine. There may be no symptoms of vesical trouble whatsoever. Usually the patient looks extremely ill and is mentally dull; he sweats profusely. The temperature is invariably high (103°–104° F.), the pulse weak and rapid (110 or higher). At the outset there is invariably a severe rigor which lasts about 10 minutes. The temperature remains elevated for five days and then takes on an undulating and a remittent character.

On physical examination the lungs, heart, and liver were found normal; an occasional mitral systolic bruit of hæmic origin has been noted. The spleen is palpable. The abdomen is usually flaccid; some patients complain of constant pain in the epigastrium. No definite information can be obtained from microscopical examination of the diarrhœic stool, which may contain some disintegrated pus cells, suggestive of a chronic intestinal ulceration.

After an initial pyrexia of some 5 to 7 days the temperature gradually falls and the pulse resumes its normal rate. All the urgent symptoms disappear; after a few days of convalescence the patient is able to resume his duties. After a further 7 to 14 days the temperature suddenly shoots up and is followed by a rigor and vomiting; the former succession of symptoms is repeated seriatim. These relapses, averaging 5 days, alternating with apyrexial periods of 8 to 14 days, recur with a remarkable regularity. The patient grows weaker and progressively more emaciated. Finally he dies of toxæmia, it may be with ascites and a profuse diarrhœa with fæcal incontinence. At this stage the liver and spleen are definitely enlarged.

In cases which progress favourably under treatment the pyrexial cycles continue but diminish in intensity, and the apyrexial periods become gradually more prolonged, as long as five weeks. Such patients rapidly put on flesh, and after a convalescence of three months, during which there is no elevation of temperature, were discharged from hospital.

Clinical signs.—Only rarely was the *urine* found chemically normal. Usually it has a specific gravity of 1010–1020, contains no albumin or sugar, but a deposit of pus cells and clumps of motile bacilli. Very rarely a cloud of albumin has been found at the commencement of the attack due to the effusion of blood, and a few red cells were then found in the urinary deposit.

In all the cases except one in which a *cystoscopic examination* was made, owing to the kind assistance of Lieutenant-Colonel Wade, R.A.M.C., the viscus presented a perfectly normal appearance. As a rule, the ureteric orifice gave no clue to the pathological condition of the kidneys. Specimens of urine obtained by ureteric catheterisation and cultured on MacConkey's medium gave growths of the causative organism. A unilateral affection of the kidney can occur.

Blood examination.—An anæmia of the secondary type was present in all cases—reduction of red cells on an average to 2,500,000. A corresponding leucopenia with a proportional rise in the total lymphocytes was the only constant and characteristic feature. The serum of three patients from whose blood the bacillus was isolated during life did not contain any agglutinins to the organism itself, even when tested in its undiluted state with living cultures. This serum was also tested against typhoid, paratyphoid A and B, Shiga, and Flexner-Y bacillus, with an invariably negative result. In two cases the organism was obtained in pure culture from the blood during life, but only during the rigors. On six separate occasions blood cultures made during the quiescent period remained sterile.

X ray examination of the lumbar regions in one case revealed no information.

Diagnosis.—Amongst diseases most closely resembling it may be mentioned malaria, undulant and relapsing fevers. In its early stages dysentery, generalised tuberculosis, phlebotomus fever, or one of the enteric group may be suspected.

The results of blood culture can be supplemented by microscopical examination and cultivation of the urine. In one patient ultimately discharged feeling quite fit an organism having exactly similar sugar reactions was recovered both from the blood and from specimens of urine from both the bladder and ureters.

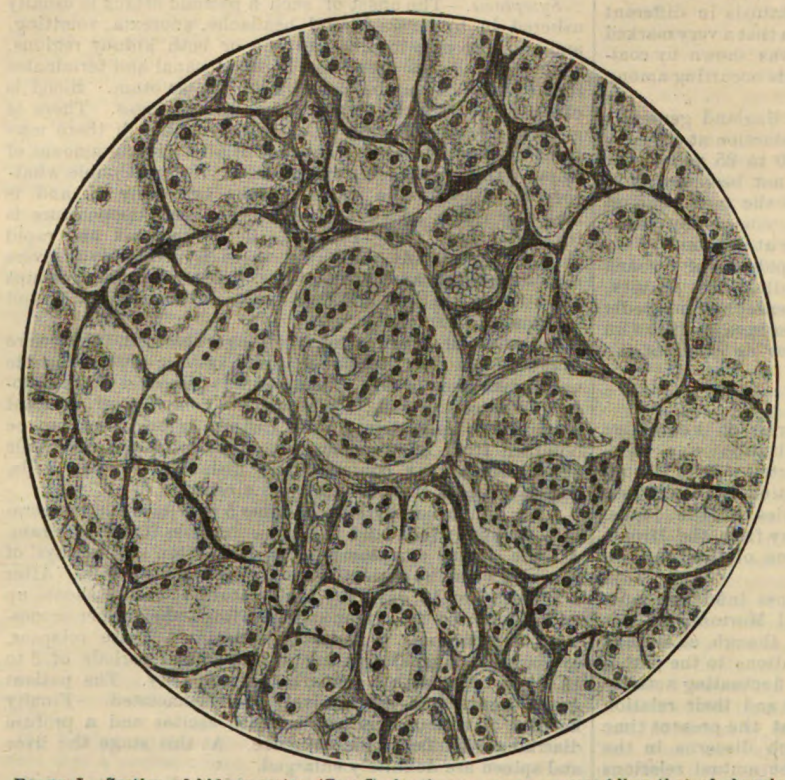

PLATE I.—Section of kidney cortex (Case 3) showing appearance resembling that of chronic interstitial nephritis. Objective, Zeiss 1/6; ocular Baker 2 × 7 = × 300 diameters. Stained by hæmatoxylin and eosin.

Treatment.—In the first few cases of *B. coli* pyæmia observed the treatment was based on symptomatic lines, together with the administration of autogenous vaccines of the bacillus as isolated from the blood (over a long period, in doses of from 5 to 120 millions), but no improvement was noted. It was decided to try intravenous eusol. The first injection was given to a patient who had been eight months in hospital on symptomatic treatment. He was then very weak and emaciated. The patient was about seven months under treatment and received nine intravenous injections of varying doses of eusol. During that period there were only three bouts of pyrexia (the last one very mild). He had increased considerably in weight, looked strong and healthy, and felt absolutely fit. Subsequently five other cases, treated on similar lines, have furnished almost equally brilliant results. (Eusol has also been successfully tried in a case of *B. coli* peritonitis following a gangrenous appendix, locally in the peritoneal cavity.)

Pathology and Bacteriology, by Captain P. H. BAHR.

Morbid anatomy.—This infection occurred coincidently and concomitantly with other diseases, such as tuberculosis, bacillary dysentery, and pellagra. In such it may reasonably be regarded as a terminal infection. Of the complicating diseases the most constant was chronic bacillary dysentery.

Two cases may be taken as examples of the effect produced by the toxins of the colon bacillus, uncomplicated by any other infection, upon the abdominal and thoracic organs. In both the parenchymatous degeneration of the heart, liver, spleen, and kidneys apparently produced by the toxins of the bacillus was very evident indeed.

Heart.—The whole organ was enlarged and the muscle pale and flabby.

Liver.—The liver was in both cases greatly enlarged (76 oz.; 100 oz.). Glandular tissue greatly degenerated. In one case there were numerous abscesses of varying size; glandular tissue was of ochreous colour; indications of commencing periportal cirrhosis. In case with biliary cirrhosis the abdomen was distended and contained 8 pints of purulent ascitic fluid, in which the bacillus was present in large numbers.

Spleen.—The spleen was very much enlarged (32 oz.; 22 oz.), with tense capsule and rounded margins. The substance was dark, soft, and diffluent. No melanin pigment found. All the characteristics of a "septic spleen." *B. coli* organisms in smears and cultures made from it in three cases.

Kidneys.—The kidneys were enlarged in both cases (in one, R. 12 oz., L. 13 oz.). Capsule stretched and adherent to many subcortical abscesses. Whole organ of pale ochre colour; cortex swollen and bulged on section; medullary striæ evident as bright yellow lines. The cortical zone itself was studded with abscesses.

The kidneys in different cases showed all intermediate stages between large swollen and small contracted granular kidney. In the latter both kidneys weighed about 4 oz. each; substance tough and fibrous; cortical zone contracted and scarred with depressed, pigmented, wedge-shaped cicatrices, in which were embedded small abscesses with thick caseous pus. (Plate I.) Evidently it would seem that the kidney may become completely fibrosed and contracted, and may then even resemble the small granular kidney of chronic interstitial nephritis, both macro- and micro-scopically. That both kidneys need not necessarily be implicated is shown by a study of one case. Here the right kidney was perfectly normal in structure both macro- and micro scopically, while its fellow contained several cortical and subcortical abscesses.

Lymphatic glands.—In the two cases which died in the acute stage the abdominal lymphatic glands were much enlarged, soft, and of a greenish colour. Retroperitoneal group and those at portal fissure implicated; in one instance pure culture of colon bacillus was obtained.

Intestines.—The intestinal ulceration present in majority of cases was mostly confined to lower part of intestinal tract. It was of a deep undermined, sinuous type, extending to muscular coat; the ulcers corresponded to transverse folds of mucous membrane. No amœbæ were found; Flexner-Y bacilli were isolated from similar ulcers in Turkish prisoners.

Microscopic pathology.—This was mainly confined to the three organs most affected—kidneys, liver, and spleen. Sections were stained by various methods; for tissue changes hæmatoxylin and eosin or hæmatoxylin and Van Gieson were employed; but by far the best pictures of the organisms in the tissues and the effects they produced upon them were obtained in sections stained by carbol-thionin blue, as well as by Ganducheau's stain (Borel's blue and eosin).

Kidneys.—Plate II. is drawn from a series of sections from different cases. In A the bacilli can be identified in the stellate arteries and in the glomeruli, whence they pass into the intertubular capillaries. There it would appear that their passage becomes blocked and, multiplying, they form large masses. They may also be found in large clumps

in the larger veins of the medulla (B). In this latter situation the organisms make their way (C) through the columnar epithelium of the ducts of Bellini into the lumen; from them they pass into the urine, together with a number of pus cells and a quantity of cellular débris. It is striking to observe the small amount of cellular infiltration in the vicinity of the organisms, and the small amount of destruction of the neighbouring convoluted tubules. The process of pus formation and cicatrisation appears to be a very gradual one. The lumen of the loops of Henle is filled with a coagulated serous exudate staining green with carbol-thionin; there is dilatation of the intertubular capillaries and a shrinkage of the glomeruli within their capsules. Eventually (Plate I.) a considerable destruction of the glomeruli, together with a dislocation and consequent desquamation of the tubular epithelium of the convoluted tubules, takes place.

In the medulla (Plate II., B) the destruction of the collecting tubules has proceeded to a considerable degree.

The cellular infiltration occurring around the collecting tubules in the medulla is composed mainly of mononuclear cells, together with smaller number of plasma cells. (C, Plate II.) In the kidneys most severely affected, few traces of the original glandular structure can be made out, and very few organisms can be seen in sections. On the other hand, the blood-vessels are packed with polymorphonuclear pus cells migrating to the cortex, and the abscesses consist of a dense collection of pus cells around greatly shrunken and destroyed glomeruli.

When cicatrisation has taken place to any large extent the changes in the glomeruli and tubules immediately bordering on the site of the abscesses resemble in their histology those seen in chronic interstitial nephritis, and may be regarded as an indication of the effects of chronic absorption of *B. coli* toxins upon normal kidney tissue. (Plate I.)

Liver.—In all sections examined there were abundant signs of a periportal infiltration resembling that seen in early alcoholic cirrhosis. There is a considerable increase in the periportal fibrous tissue, together with an outpouring of round cells. The liver cells themselves have undergone fatty degeneration.

In one case the section passes through a small hepatic abscess. The main type of cell in the exudate is, apparently, the small mononuclear, very few polymorphs being visible. The abscesses in the liver appear to have no definite limitation, and there has been no attempt at fibrous tissue formation; in addition the hepatic cells in the immediate vicinity are considerably damaged.

Spleen.—Collections of organisms can be made out lying free in the venous sinuses of the spleen pulp, or sometimes in the centre of a Malpighian corpuscle and surrounded by collections of small mononuclear cells. The hypertrophy of fibrous tissue is marked both in the capsule and in the trabeculæ. This fibrosis of the spleen appeared to be common to all the cases of the series.

Bacteriology.—The morphology of the bacilli in these cases was studied in smears and sections made from the organs and in cultures stained by Romanowsky or thionin methods.

In the tissues they appeared as fusiform bacilli, with marked bipolarity, together with the appearance of diplo-bacillary forms; these were also seen in young agar cultures, indicating, apparently, a rapid proliferation on the part of the organism. In smears of the spleen stained by Giemsa this bipolarity was so pronounced as to give the impression that one was dealing with an infection of *B. pestis*. All cultures were Gram-negative.

All the strains isolated were either non-motile or perhaps feebly so.

Sugar reactions, &c.—In the reactions on the sugars a very considerable difference was noted, and found constant for the same strain of bacillus. From the clinical resemblance of these cases, from which apparently distinct organisms were obtained, we cannot bring ourselves to regard the variations of these sugars, not even of such an important sugar as lactose, as marking such a great diversity in the nature of the organisms involved, for it is very evident from post-mortem studies, as well as from microscopical sections, that their pathogenic action on the tissues was in all cases almost identically the same.

According to their reactions with five sugars in peptone water the organisms isolated can be divided arbitrarily into nine groups (A to I), of which three—A, E, and F—do not ferment lactose, and I cannot find any record of these having been previously classified. In the table are shown the characters of these organisms after 24 hours' incubation in 1 per cent. sugars and 1 per cent. peptone water.

The commonest type recorded is D, which corresponds with the *Bacillus neapolitanus* of Emmerich, and occurred 8 times out of 21 organisms isolated. It was isolated in pure culture from the blood, right kidney, spleen, urine, and rectum of Case 8. Cultures from the left kidney, liver, mucous cyst from rectal wall of same case gave slightly different reactions (G, I). There is reason for presupposing that they are merely variants of the same bacillus.

Type H would seem to correspond to *B. oxytocus perniciosus* (MacConkey); it was isolated twice from spleen and liver of same post-mortem.

Type I, isolated twice, corresponds in its reactions to those given for *B. acidi lactici* (Hüppe).

The remaining types B, C, and G, without reference to more extensive literature, cannot be placed in any classification.

Pathogenicity.—A limited number of experiments were made with broth cultures and agar emulsions of these organisms on rabbits. From ½ to 1 c.cm. of 24-hours old broth culture was injected intravenously, but only produced a transient indisposition. Opalescent emulsions of agar slopes after 24 hours' incubation were then tried in doses of 1 c.cm. Two types of the organism (B and C) proved pathogenic. Type A would appear to have but slight pathogenic properties for rabbits.

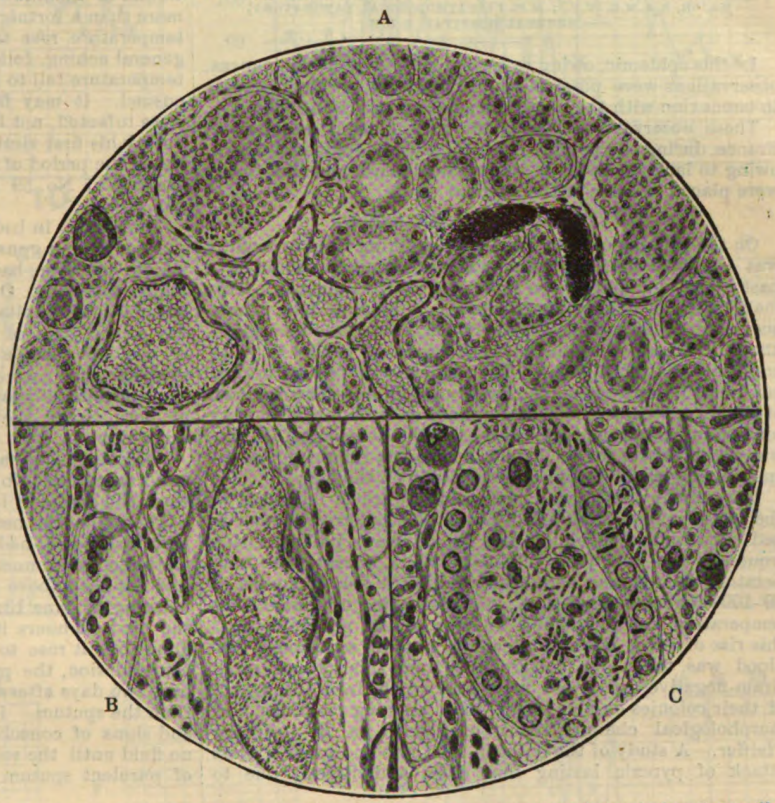

PLATE II.—A. Section of renal cortex showing emboli of organisms in stellate arteries, glomeruli, and intertubular capillaries. Note the apparently normal appearance of the adjacent convoluted tubules. Objective, Zeiss 1/6; ocular, Baker 2 × 7 = × 200 diameters. (Case 3.)
B. Section of renal medulla showing a large collection of organisms in a medullary vein, with destruction of the tubular epithelium and dilatation of adjacent capillaries. Zeiss 1/6; ocular, Baker 8. × 300 diameters. (Case 7.)
C. Section through a duct of Bellini showing the passage of bacilli through the tubular epithelium and numbers in the lumen with polymorph cells and débris. Zeiss 1/12; ocular, Baker 8. × 1000 diameters. (Case 6.) Stained by carbol-thionin.

Type.	Glucose.	Lactose.	Saccharose.	Mannite.	Dulcite.	Indol.	Neutral red.	Milk.

We wish to thank Lieutenant-Colonel Vickerman, R.A.M.C., for permission to record these cases, and also for much help and encouragement. Our thanks are also due to Lieutenant-Colonel Wade, R.A.M.C., consulting surgeon to the Forces in Egypt, for kind and continued assistance.

OBSERVATIONS ON A SMALL LOCALISED EPIDEMIC OF INFLUENZA,

WITH SPECIAL REFERENCE TO THE INCUBATION PERIOD.

BY MICHAEL G. FOSTER, M.D., F.R.C.P. LOND.,
MAJOR, R.A.M.C. (T.F.); M.O. I/C MEDICAL DIVISION, —— GENERAL HOSPITAL, B.E.F.;
AND
H. ANSTEY COOKSON, M.B., F.R.C.S.ED., D.P.H. CAMB.,
MAJOR, R.A.M.C. (T.F.); M.O. I/C PATHOLOGICAL LABORATORY, —— GENERAL HOSPITAL, B.E.F.

IN this epidemic, owing to a combination of circumstances, observations were possible which furnish a few definite data in connexion with the incubation and spread of influenza.

These observations were made at a general hospital in France during the height of the influenza epidemic, where, owing to lack of beds in the medical wards, medical cases were placed in some of the surgical wards.

The Cases in Beds 62, 63, and 61.

On the evening of June 6th a man suffering from bronchitis was admitted into a surgical ward in which for some days past no patient had shown signs of a medical malady. This man had gone sick with a febrile attack on June 1st; cough, accompanied by copious expectoration, soon made its appearance. On admission he had a temperature of 99° F., with crepitations at both bases. The temperature fell to normal on June 10th and the signs rapidly cleared up. The duration of the fever, the presence of crepitations, and rapid recovery tend to indicate that this was a case of influenza. This man was notably dirty in his habits, constantly failing to use the sputum mug and spitting promiscuously on the floor.

The arrangement of the beds in the ward is indicated in the accompanying diagram. The patient referred to was in bed 62. In the adjoining bed, No. 63, was a patient with a wound of the knee-joint infected with *S. aureus;* the temperature in this case had been running a steady course of 99–100° for some days past; on the evening of June 9th his temperature rose to 103·6°. In view of the possibility that this rise of fever might indicate a general septicæmia the blood was taken for culture, and from this culture small Gram-negative rods were recovered which, from the aspect of their colonies on blood-agar, their staining reactions, and morphological characteristics, conformed to *B. influenzæ* Pfeiffer. A study of the chart in this case indicates a short attack of pyrexia lasting four days, and directly due to *B. influenzæ* engrafted upon a condition of chronic septic absorption.

The patient in the bed No. 61 was suffering from a gunshot wound of the arm, accompanied by irregular fever ranging from 98–102°. In this case, again, there was a sudden rise of temperature to 104° on the afternoon of June 9th, accompanied by conjunctivitis, cough, and some expectoration; the temperature remained 104° or slightly lower until the 11th, finally falling somewhat abruptly to subnormal on June 14th. Pfeiffer's bacillus was not recovered from the sputum in this case. The duration of the pyrexia, taken in conjunction with the presence of catarrhal symptoms in the one case, and bacteriological proof of invasion by Pfeiffer's bacilli in the other, warrant the assumption that both were cases of influenza. That the infecting agent was the patient who came in bed No. 62 before midnight on June 6th admits of little doubt. The period of incubation can therefore be fixed as from midnight on June 6th to 4 P.M. on June 9th, a period of 64 hours.

The Other Cases.

The patient in bed 60 had a compound fracture of the humerus, the temperature had been normal for the past 14 days. On the morning of June 11th he had an attack of shivering and the temperature rose to 100°; he had general pains; the temperature fell to normal on the evening of the 12th.

Next to the last patient in bed 59 was a man with a wound of the knee; the temperature had been normal for more than a fortnight. On the afternoon of June 11th the temperature rose to 104°, accompanied by shivering and general aching, followed by cough and expectoration. The temperature fell to normal on the 13th, and a rapid recovery ensued. It may fairly be assumed that these two cases were infected, not by the original importer of the disease, but by his first victim, the patient in bed 61. On this hypothesis the period of incubation would be exactly 48 hours in the case of No. 59 and some six hours less in the case of No. 60.

The patient in bed 64 adjacent to one of the first cases suffered from a gunshot wound of the chest (non-penetrating) which, however, had not given rise to any degree of fever higher than 99°. On June 11th the temperature rose to 103° with cough; crepitations were audible at the left base. Next day a small area of consolidation was observed at the angle of the left scapula. The temperature fell, followed by a secondary rise, accompanied by signs of a small patch of consolidation at the right base. Rapid resolution took place at both bases, the temperature falling to normal on the sixth day.

Assuming this case to have been infected from his left-hand neighbour, No. 63, who was a bacteriologically proved case, the period of incubation would be exactly 48 hours.

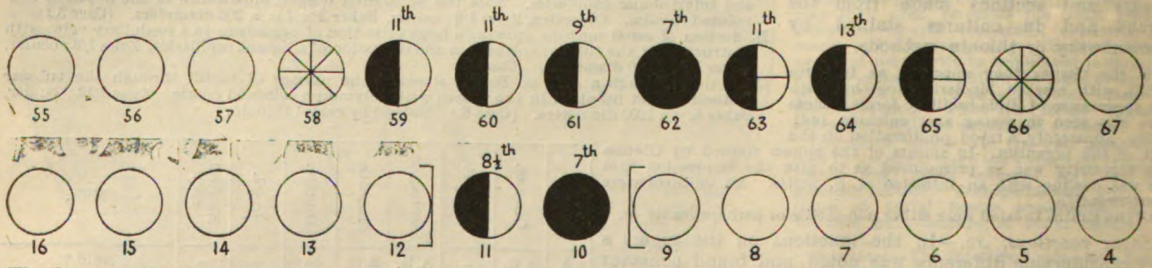
The patient in bed 65, the right-hand neighbour of last-mentioned case, had been in hospital suffering from inflammation of the connective tissue of the feet. His temperature had not been above 99° during his stay in hospital. On the morning of June 13th his temperature rose to 100°, and for the next 48 hours it ranged between 99° and 100°, until on June 15th it rose to 103°. The left base showed signs of consolidation, the pneumonic process spreading to the right base two days afterwards. Pfeiffer's bacillus was recovered from the sputum. In this case resolution was delayed, fever and signs of consolidation persisting. Exploration yielded no fluid until the sudden expectoration of a large quantity of purulent sputum and the appearance of the signs of a cavity at the left base indicated the presence of a pulmonary abscess. X rays confirmed this diagnosis. The sputum contained pneumococci, but in the later stages *B. Pfeiffer* could not be recovered.

This patient made a good recovery. Assuming this case to have been infected from his right-hand neighbour, the period of incubation proves to be almost exactly 48 hours.

In this group of seven cases there were four distinct periods of infection, this infection beginning at the centre bed 62 and spreading from bed to bed on either side. In every case, moreover, the infection spread directly from bed to bed; in no case was the orderly sequence of a systematic march departed from. The limitation of the series is in all probability attributable to the fact that two beds, Nos. 66 and 58, stood empty during the whole epidemic.

Two cases occurred on the opposite side of the ward, which are shown in the diagram as Nos. 11 and 10.

Diagram of Beds in a Surgical Ward of a Military Hospital.



The diagram illustrates the narrow radius within which infection from influenza takes place. The infection began from Bed 62 into which a man suffering from bronchitis was admitted on June 6th. Adjoining and opposite bed-fellows were stricken with influenza on the dates shown. Key to Diagram appears on opposite page.

Temperature Charts of an Epidemic of Influenza localised in a Surgical Ward. The bold number at the foot of each chart refers to the position of the bed as given in the diagram. The crosses on the charts denote the beginning and end of the influenzal febrile movement.

It is difficult to be sure whether No. 62 on the opposite side was responsible or whether No. 10 was himself infected before admission to the hospital. This case was a medical case admitted under similar circumstances to No. 62—namely, pressure on medical beds due to the general epidemic. This man was a slight gas case and was admitted about midnight on the 6th, afebrile on arrival, but had a sudden rise of temperature at 12 P.M. on the 8th, a period of 48 hours after admission. His ailment showed pyrexia, rhonchi, and crepitations at the left base. His recovery was rapid, the laryngitis, due to gas, remaining unaltered during the whole period. His left-hand neighbour, No. 11, suffered from fracture of the right and left humerus, and this case had a sudden rise of temperature on the 8th, shivering and coryzal symptoms, and an ear discharge. This cleared up very rapidly. The incubation period was between 35 and 40 hours.

The limitation of spread from these cases may be explained by the fact that although the beds were occupied, yet elaborate cross-pieces for splints materially increased the space between the beds, thus interposing the barrier to further spread.

Summary.

The ailment from which all these cases were suffering appears without doubt to be influenza, both from the positive bacteriological results in two cases out of nine and also from the clinical observations. As regards the latter, it is interesting to note that the following symptoms were presented by one or other case, and that the duration of the illness was either long or short: (1) septicæmia; (2) coryza; (3) bronchitis; (4) broncho-pneumonia; (5) otitis media; (6) body pains, &c. In all these cases the incubation period was about 48 hours, the cases in which possibilities of accurate observation were greatest were those which approximated most closely to a 48-hour period.

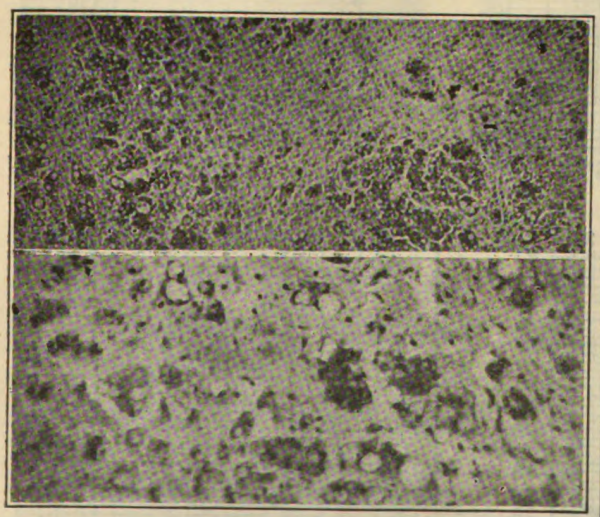
These observations illustrate two factors in the spread of influenza. Firstly, the narrow radius within which infection takes place; secondly, the shortness and apparent punctuality of the incubation period. Both these factors help to explain the rapid spread of epidemic influenza.

SUPPLEMENT TO A NOTE ON

"ACUTE YELLOW ATROPHY" (?).

BY ERNEST GLYNN, F.R.C.P. LOND.

THE following microphotographs illustrate the condition of the liver on microscopical examination in the case of the female munition worker, aged 20, who died suddenly of acute toxic jaundice (?) nine months after leaving the T.N.T. filling-room. A full note on the case appeared in THE LANCET of Oct. 26th, pp. 555–6.



Upper half.—Section of liver, × 150, showing large necrotic areas and portions of persisting but fatty lobules.
Lower half.—Section of liver, × 400, showing (right quarter) unusually cirrhotic area and (left bottom corner) necrotic area. Fatty liver cells are also seen

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF MEDICINE, EPIDEMIOLOGY, AND PATHOLOGY.

Encephalitis Lethargica.

A COMBINED meeting of these sections was held on Oct. 22nd, Surgeon Rear-Admiral Sir HUMPHRY ROLLESTON, President of the Society, being in the chair, when a discussion took place on Encephalitis Lethargica, a brief note on which has already appeared in our columns.

Pathology.

Lieutenant-Colonel F. W. MOTT, R.A.M.C. (T.), gave a résumé of the results of the examination of two brains which was sent through him by M. Marinesco, professor of neurology at Bucharest, who had been working for some time past in the pathological laboratory of the Maudsley Neurological Clearing Hospital. Disseminated miliary or punctiform hæmorrhages visible to the naked eye existed in the grey matter in the neighbourhood of the floor of the fourth ventricle, the aqueduct of Sylvius, and even the third ventricle, and were also found in the posterior part of the pons and the peduncles. The cerebral cortex, except for congestion of some of the vessels of the lepto-meninges, had shown in these two cases neither macroscopic nor microscopic lesions. On the contrary, the first segment of the spinal cord, which was the portion of the cord available, had presented the same histological lesions as the pons, bulb, and peduncles. Microscopical study of the above-mentioned regions had demonstrated the existence of four kinds of lesions: 1. Infiltration of the walls of the small vessels, and especially the veins, consisting of lymphocytes and plasma cells in the adventitia, disposed in several layers. The endothelium and fibroblasts might also take part in the inflammatory process. 2. Foci of interstitial inflammation consisting of neuroglia cells of several kinds, including large cells with voluminous excentric nucleus and many fibrillar prolongations, lymphocytes, and polynuclears. The foci of interstitial inflammation appeared sometimes to be altogether independent of vascular infiltrations, and might occur in the roots of the nerves—e.g., hypoglossal, pneumogastric, &c. 3. Lesions of the nerve cells, which did not correspond with those usually seen in infantile paralysis. There was dissolution of the *soi-disant* Nissl bodies, relative achromatosis, reduction in volume of the cellular body and of the number of prolongations and multiplications of the satellite cells, but only exceptionally was there evidence of neuronphagia, as was described by Economo. 4. The foci of hæmorrhage, the most obvious microscopic change, were seen to be much more numerous when microscopic examination was made. These hæmorrhagic foci remained circumscribed around the walls of the small vessels, and red corpuscles were mingled with the cells of inflammatory infiltration, or they constituted a kind of covering and floated about around the vessels. In spite of the very great number of hæmorrhages the vessel wall did not appear to be necrosed, but sometimes a solution of continuity of the vessel wall could be seen. From microscopic investigation of these two cases, M. Marinesco drew some conclusions upon the nature of the disease. He regards lethargic encephalitis as a disease entirely different from botulism, from the hæmorrhagic poliomyelitis of Wernicke, from the poliomyelitis of Heine-Medin, and from sleeping sickness. Like these two last diseases, it was an infectious inflammatory disease, but the nature of the infectious germs had not yet been determined. It was distinguished from botulism by its symptomatology and by the four above-mentioned histological lesions. The vascular lesions, due to the presence of an infiltration of the walls of the vessels by migratory elements, were absent in botulism, and the readily recognisable *Bacillus botulinus* had not been found in these cases. Colonel Mott then showed photomicrographs illustrating the chronic inflammatory conditions of the perivascular lymphatics in sleeping sickness and cerebro-spinal syphilis, in which there was definite infection by a specific organism, and which might be accompanied by somnolence. In

epidemic encephalitis and the bulbo-pontine encephalitis of Heine-Medin disease, which, as Wickman had shown, was a form of anterior poliomyelitis, somnolence was a frequent symptom, passing on to coma. Epidemic encephalitis was an acute inflammation of the sub-adventitial perivascular lymphatics, and was characterised by naked-eye hæmorrhages in the pons, the medulla, the peduncles, and around the third ventricle. Microscopic examination showed not only lymphocytes and plasma cells in the lymphatic sheaths of the arteries and veins, but large numbers of polynuclears, and the inflammation was so acute that there were hæmorrhages, not only into the lymphatic sheath and peri-adventitial space, but into the tissues around. There was proliferation of neuroglia cells around the vessels and in the nervous tissue in the proximity of the inflamed vessel. He could find no essential difference between this epidemic encephalitis with its characteristic clinical symptoms of fever, headache, oculo-motor, facial and bulbar symptoms of difficulty in swallowing, paralysis of soft palate and respiratory symptoms, and the ponto-bulbar encephalitis of Oppenheim and Cassirer, and observed frequently in the epidemic described by Wickman. In the Heine-Medin disease, as in cerebro-spinal syphilis, different forms arose according to the maximum seat of the lesion, and this might be explained by supposing that the primary seat of invasion of the lymphatics of the nervous system varied in different cases and in different epidemics. Thus, the spinal cases might start from the intestines and find access to the spinal cord by the lymphatics surrounding the lumbo-sacral arteries; lesions in the bulbo-pontine and upper spinal region might start from infection of the lymphatics surrounding the vertebral artery when the throat and nose was the primary seat of invasion of the peri-arterial lymphatics, or by the infection of the internal carotid when in the encephalitic or meningeal forms. It was said that this epidemic of ponto-bulbar encephalitis could not be the same as Heine-Medin disease, for the cerebro-spinal fluid obtained by lumbar puncture contained no lymphocytes. Captain C. R. Box had had cases in which lymphocytes had been found. It appeared that when the meninges were affected lymphocytes and albumin were certain to appear in the cerebro-spinal fluid.

Observations on Blood Counts and Cerebro-spinal Fluid.

Dr. P. N. PANTON said that the examinations made of cases in the clinical laboratory of the London Hospital consisted in investigations of the leucocytic content of the blood and the protein and cellular contents of the spinal fluid. The results were compiled and published by his colleague, Mr. S. K. Vaidya, in THE LANCET of Sept. 7th, 1918, and he proposed to give very briefly a summary of these findings. Twenty of the most typical cases were examined, and it was probable that the diagnosis was incorrect in two only. In both these cases the error in diagnosis was indicated by the laboratory examination. One case had a leucocytosis of 21,200 per c.mm., by far the highest count of the series, and proved to have lobar pneumonia. In the other tubercle bacilli were found in the spinal fluid during life and miliary tuberculosis post mortem. In the remaining cases the average leucocyte count was 7600 per c.mm., and the relative proportions of the cells were about normal. An occasional somewhat higher leucocyte count was explained by the presence of a septic rash or some other complication. The spinal fluid was in all cases clear and without any coagulum on standing, such as was found in tuberculous cases. The protein was never more than slightly increased, and the cellular content was either normal or slightly increased also, the type of cell being always lymphoid. In some cases he thought that the protein excess, which, though not great, was constant, was greater than should have been expected from the small number of lymphocytes found. Although these changes were very slight they appeared to them to be constant. The value of leucocytic, and in particular of spinal fluid, examinations as a means of *excluding* diagnoses of epidemic encephalitis was abundantly manifest in numerous cases of other diseases occurring during this epidemic, but not included, with two exceptions, in the series.

Dr. F. G. CROOKSHANK said that in describing the cerebro-spinal fluid examination it was necessary to state the day of the disease on which the fluid was taken, as the cell count, &c., differed from day to day.

Epidemiology.

Dr. W. H. HAMER pointed out that just as in 1915 the so-called epidemic of cerebro-spinal fever was really only a small part of an influenza prevalence, so in the epidemic encephalitis of the spring of 1918 a particular cluster of symptoms was once more being singled out for scrutiny, and that here, again, the epidemic, so-called, was merely part and parcel of a prevalence of influenza. During the last ten years evidence had been collected, however, clearly showing a close association between outbreaks of poliomyelitis, polioencephalitis, cerebro-spinal meningitis, and prevalences of influenza. He referred to Brorström's demonstration of the influenzal nature of poliomyelitis, to the London evidence relating to the common origin of cases of influenza and of cerebro-spinal fever, and to the similar conclusions arrived at by an Army bacteriologist from study of the 1915 outbreak in camps. The proof that epidemic lethargy was no new disease was writ large in Hecker and in Creighton,[1] and was now being followed out in detail by Dr. Crookshank in his Chadwick lectures in course of being delivered. In spite of all this there was a disposition, in some quarters at the present time, to claim that the epidemiological teaching must be brushed on one side, and reliance placed exclusively upon niceties of laboratory technique. In view of the fact that "Spanish influenza" had followed hard upon the heels of epidemic encephalitis, he ventured to plead, once again, for the epidemiological point of view. These "new diseases" could not be completely understood by making cell counts and cultivating various strains of organisms; nor fully comprehended by insisting upon the fact that particular structures had been picked out in the cerebro-spinal nervous system, and that the lesions were here at one level and there at another; nor satisfactorily explained by focusing attention upon some particular sign or symptom, whether it were sweat, lethargy, paralysis, an exanthem, or some evidence of involvement of the pulmonary, nervous, or gastro-intestinal systems, and by considering each phase of the epidemic prevalence in relation thereto and studying it apart from all the other phases. Recognition of the epidemiological point of view really implied, he submitted, a return to Sydenham's method. Creighton had declared that there was something more than accident in the association between epidemics of influenza and epidemics of "ague." Study of the last named showed clearly that they were not, of course, outbreaks of malaria, but precisely those very gastro-intestinal, pulmonary, and nervous manifestations which we were now beginning to realise actually constituted part and parcel of influenza prevalences.

Report of Local Government Board.

Lieutenant-Colonel S. P. JAMES (Local Government Board) said that Sir Arthur Newsholme had authorised him to give a brief summary of the results of an inquiry into encephalitis lethargica recently carried out by the medical staff of the Local Government Board in collaboration with the Medical Research Committee. Owing to printing difficulties the issue of the report of this inquiry had been greatly delayed. The summary he gave was abbreviated from Sir Arthur Newsholme's general review which prefaced the report. In its initial stages last April the inquiry was concerned chiefly with an investigation of the hypothesis that the illness was a manifestation of botulism. In connexion with that view Dr. J. McIntosh, on behalf of the Medical Research Committee, carried out a complete bacteriological investigation, and Dr. G. C. Hancock and Dr. Pearse, of the Food Branch of the Board's Medical Department, personally investigated, from the point of view of a possible food origin, 58 cases reported up to May 7th. The result of these preliminary inquiries was that neither on the bacteriological nor on the epidemiological side could any direct or indirect evidence be obtained of an association of the illness with the *Bacillus botulinus* or with infection from food. In addition to proving that the illness was not due to food, the results of the preliminary inquiry pointed to a possibility that it might be one of the many forms of the disease, or group of diseases, to which nosologists at present attach the indiscriminative label "Heine-Medins'che Krankheit," of which infantile paralysis—officially termed acute poliomyelitis—was the commonest

[1] THE LANCET, 1906, i., 569, 655, 733.

type of illness. It was found, however, that from infantile paralysis the present illness differed very strikingly, not only in the localisation of the paralysis and some other equally obvious signs, but in its age incidence, seasonal prevalence, course, duration, and fatality.

In these circumstances it was decided to carry out a more complete clinical and epidemiological study of the illness than had been attempted in regard to the first 58 cases. The Public Health Department of the London County Council agreed to investigate all cases in the London area. Up to the end of June the number of cases in the London area inquired into was 107 and the number in the provinces was 121. Apart from these special inquiries Dr. A. S. MacNalty was deputed to undertake a detailed personal study of the clinical symptoms of the illness, conferring with Sir William Osler, Regius professor of medicine, University of Oxford, and with Major George Draper, of the United States Army Medical Corps, who examined and reported on cases in Birmingham, Leicester, Oxford, and other localities. On the bacteriological side, in addition to the research in connexion with a possible food origin, the problem of the nature of the illness was attacked from the point of view that the virus might be closely allied to, or perhaps identified with, that of acute poliomyelitis; and in this line of research animal experiments were begun as soon as the necessary monkeys could be obtained. In addition Sir Walter Fletcher, F.R.S., secretary to the Medical Research Committee, secured the services of Professor G. Marinesco, of Bucharest, for the examination of specimens from fatal cases of the disease.

Results of Investigations.

The accounts given by all these observers might be summarised very briefly as follows: 1. For identification and description it was decided to follow von Economo in terming the illness encephalitis lethargica, a name which had the right of priority and indicated a characteristic clinical feature. 2. Dr. MacNalty, from his clinical study, concluded (*a*) that in its essential primary features the illness had a characteristic and constant symptom series of its own; (*b*) that between this symptom series and that of the rare forms of poliomyelitis with which alone it could be confused the clinical differences were more marked than the resemblances. 3. The results of the epidemiological inquiries were to the effect that encephalitis lethargica was not a form of acute poliomyelitis, and that its presence and epidemic prevalence depended on conditions other than those necessary for the presence and epidemic prevalence of that disease. 4. Both Professor Marinesco and Dr. McIntosh, as a result of their separate researches, arrived independently at the conclusion that encephalitis lethargica, as it appeared in the present outbreak, was identical with the illness described by von Economo in Austria and Professor Netter in France, and that it was a disease sui generis anatomically and clinically distinct from analogous affections.

It still remained to ascertain what the nature of the disease was rather than what it was not. Various hypotheses had been suggested by different workers engaged in the inquiry, but the view which appeared best to agree with present knowledge was that encephalitis lethargica was one of a group of diseases in which, as in cerebro-spinal fever and acute poliomyelitis, the pathogenic agent was much more generally present in the human organism than the clinical evidence implied. As regards cerebro-spinal fever this was no longer an hypothesis, but a well-established observation. In that condition the specific reaction named cerebro-spinal fever arose in one or other of two ways: first, as the result of a breakdown in the immunity to the effects of the virus which the individual who harboured it had up to that time enjoyed; secondly, as the result of a non-immune person becoming infected with a strain of the virus which had attained the degree of pathogenic action described as specific. During severe epidemics evidence could sometimes be obtained that cases of cerebro-spinal fever arose in both these ways, but during inter-epidemic and mild epidemic periods it was seldom or never possible to obtain evidence that the illness was infectious: at such times cases of the disease were always scattered sporadically, and, except the patient himself, they cannot be traced to any known source of infection.

This was the view that best explained the irregular, widespread, sporadic distribution of encephalitis lethargica. Until further research yielded precise information we might assume that many people harboured the organism of the illness—perhaps as a harmless saprophyte, perhaps as a "conditional parasite," perhaps in the stage when it must be termed a "specific pathogenic" parasite—and that in certain of these persons there occurred for some unknown reason either an enhanced virulence of the parasite or a lowered resistance of the tissue cells, or both, the result being that the stimulus of the parasite overcame the resistance of the tissue cells and the host suffered from the effects of the virus which previously he had harboured with impunity. This explanation implied that the key to the problem rested not in the purely bacteriological view of the causation of disease, but in the wider view that disease resulted from the interaction of several factors of which changes in the properties of the tissue cells on the one hand, and in the provoking stimulus or pathogenic agent on the other, were the chief. The view emphasised the rôle of the individual in the origin and progress of the disease, and the practical indication would seem to be to enlist all the resources of personal and public hygiene in an endeavour to influence favourably the potential energies of body and tissue cell resistance, especially in individuals who might seem to be predisposed to a disease of this nature if they happened to become a host of its parasite. At the same time, it was clearly of importance to pursue research, both to ascertain what pathogenic agent was concerned and into the factors of individual predisposition and correlated resistance, the variations of which were subject to so many influences. The first necessity for these studies was early and complete information of all cases of the disease in different parts of the country, and for this reason the Local Government Board had decided, as a temporary measure, to make encephalitis lethargica compulsorily notifiable for a period of one year.

Colonel James then reviewed briefly the relevant epidemiological data collected up to the end of June, and thought that the evidence adduced, in both quantity and kind, supported the conclusions (1) that the illness under consideration was not a form of acute poliomyelitis; (2) that its presence and its prevalence in epidemic form depended on conditions other than those necessary for the presence and epidemic prevalence of that disease. He displayed charts comparing the seasonal incidence of poliomyelitis and encephalitis lethargica and maps comparing the distribution of the two diseases.

Description of the Disease.

Dr. A. S. MACNALTY described the condition of encephalitis lethargica occurring in the recent outbreak as an acute illness in which nervous localising signs might or might not be present. There were three types: 1. A type displaying general disturbances of the functions of the central nervous system but without localising signs. 2. Types with nervous localising signs: (*a*) clinical affection of the third pair of cranial nerves; (*b*) affections of the brain stem and bulb, with local lesions of other cranial nerves; (*c*) affections of the long tracts—e.g., pyramidal, pre-pyramidal, and upcoming afferent tracts; (*d*) ataxic types (involvement of cerebellar mechanism); (*e*) affections of the cerebral cortex; (*f*) types indicating some evidence of spinal cord involvement; (*g*) polyneuritic type. 3. Mild or abortive types, with or without localising signs in the central nervous system. The *incubation period* was probably variable. The *prodromal period* commonly ranged from the first to the seventh day, but might be as protracted as three weeks, during which occurred lethargy, headache, giddiness, and diplopia, as well as lassitude, fatigue, vomiting, and diarrhœa. *The acute manifestation* included slight early rise of temperature (to 101° or 102° F.), marked asthenia, catalepsy, stupor (alternating with nocturnal delirium), emotional changes, changes in speech (which became either nasal, monotonous and slurred, or chattering, rapid and unintelligible), fibrillary movements, and choreic movements of face, trunk, and limbs. Muscular pains, hyperæsthesia, retention or incontinence of urine, incontinence of fæces, sweating, skin eruptions, and dysphagia might also occur. Marked constipation was the rule. The rapid, complete, or partial clearing of the paralysis was the most remarkable feature of the types with nervous manifestations. Mild or abortive types were rare. Recovery was gradual and tedious, chiefly on account of the great prostration and muscular weakness. Death appeared to be due to paralysis of the respiratory centre in the medulla, and was preceded by intensification and frequency of delirious attacks, deepening of the stupor, and coma. After-effects noted were:

(1) alteration in the mental condition; (2) persistence of cranial nerve palsies; (3) the subsequent appearance of paralysis, apparently of spinal origin; and (4) athetosis. He concluded that, though the disease resembled poliomyelitis, it differed from it in important respects and displayed characteristic symptoms. It was possible that the accepted classification of poliomyelitis had been made on too wide a basis, and certain cerebral, ponto-bulbar, and ataxic types might have been examples of the clinical forms observed in this outbreak. Cases of poliomyelitis and encephalitis had been known to occur side by side. He thought the relationship between them might be comparable to that existing between typhoid fever and paratyphoid.

Clinical: A Series of 16 Cases.

Lieutenant-Colonel A. J. HALL spoke of his experience of 16 undoubted cases which came under his immediate observation. The epidemic in Sheffield differed from the whole, in that there was not one fatal case throughout. His cases included persons of each decade up to 70 years. Only two were under 10 years. The sexes were about equally represented. The epidemic began early in March, and was practically over by the end of April. The *mode of onset* varied considerably. In five the onset was sudden, in the remainder it might be described as gradual.

Symptoms and signs.—The three cardinal signs in a typical case were *lethargy*, *general asthenia*, and *cranial nerve palsies*. One or even two of the cardinal signs might be slight or absent, but as a rule the clinical picture was chiefly due to the asthenia and lethargy. In one of the cases the lethargy was slight and the cranial palsies limited to a slight ophthalmoplegia, but the general asthenia was so extreme that the patient gave a typical picture of immobility, being unable to turn over in bed and hardly able to move arms or legs. Another case within 24 hours developed almost complete facial diplegia, whereas there was no lethargy or asthenia throughout. He emphasised the importance of considering the three cardinal signs as a whole; any one of them might predominate or might be slight or absent. In most cases the cranial nerve palsies formed but a small part of the whole symptom-complex.

Prodromal period.—In most cases there was a distinct interval between the onset of illness and appearance of characteristic symptoms, and this varied widely. It was usually a few days—about one, to four or five—but in some of the cases had been not less than 10 days. The onset of the cardinal signs might be sudden, but was usually ingravescent, and this was particularly true of the cranial palsies. They took some time to develop fully, and might vary in extent from day to day. The general asthenia tended to make the facial palsies less obvious than usual. *Ophthalmoplegias.*—Strabismus of variable extent, inequality of pupils, and nystagmus were commonly present. The last named was sometimes of an irregular and incoördinate kind. *Fever* was noted in many cases, sometimes severe and prolonged, but might be slight, even in a severe attack. *Lethargy* was perhaps the most striking feature of most of the cases. It was not true sleep. Often the patient was surprisingly awake to what was going on. Many who were stuporose all day became delirious at night, returning to stupor next day. Sometimes the delirium was of a foolish kind and suggested hysteria. *Tremors.*—In one case tremors with asthenia were the chief symptoms. *Speech.*—During the lethargic period this was often affected. In one case there was a distinct hurried or festinating speech, such as is sometimes observed in paralysis agitans.

Results.—All the 16 cases were still alive, most had been seen within the past few days, and reports from their medical attendants had been received of others. Group A consisted of 7 cases in which recovery was complete and absolute. Group B contained 6 cases in which recovery was practically complete, some slight trace of illness being left behind. In Group C there were 3 cases, and these after six months were still far from recovery. In each case the present incapacity was due to involvement of the trunk and limb muscles generally, the cranial palsies having disappeared completely or almost so.

The points for discussion might be summed up as follows: Was this or was it not an epidemic of poliomyelitis? If it was not, then it might be either an entirely new disease or one that until recent times had not been observed in epidemic form. Lethargy and asthenia, so severe and prolonged in most of the cases of encephalitis, had not been recorded as occurring in typical cases of poliomyelitis, sporadic or epidemic. He could not think that anyone would consider the term "sleeping sickness" descriptive of poliomyelitis in general, yet it would not be an inappropriate name for this epidemic. Except for the palsies there remained little in these cases of encephalitis which was common to them and to poliomyelitis. Even the palsies presented striking differences in the two diseases. In poliomyelitis the onset tended to be rapid and maximal; the regions affected were usually those innervated from the spinal cord; the distribution was often unilateral, and they frequently left permanent residual effects of greater or less extent in the areas first attacked. In the recent epidemic the paralyses were typically of gradual ingravescent onset; they almost always affected regions innervated by cranial nerves and were often bilateral. So far as present evidence was available they usually left no permanent residual effects in the area first affected. We knew that many nerve poisons—e.g., diphtheria, *B. botulinus*, lead, alcohol, &c.—showed a peculiar predilection for certain particular parts of the nervous system; in these cases of epidemic encephalitis there seemed to be such a definite selective action at work. It had been pointed out that poliomyelitis in its epidemic form was characterised by the multiformity of the sites affected. The cases of the recent epidemic were notable for the uniformity of the sites affected. With regard to the possibility of this being an old disease which had only recently been recorded in epidemic form he had no proof to bring forward. A similar epidemic appeared about the same time in 1917. In course of time records of sporadic cases of a similar type might be found as abnormal or exceptional varieties of influenza or poliomyelitis, &c. Such a line of inquiry seemed worth consideration, but in any case the final decision rested with the pathologist. Photographs were displayed on the epidiascope to show the mask-like countenance, the lethargy, and the posture of patients in bed.

Statistical Observations on 127 Cases.

Dr. CROOKSHANK gave statistics of 127 cases observed by him early in this year, and considered by him examples of Heine-Medin disease, 120 occurring at the London Hospital, 4 at the North-West London Hospital, and 3 private cases. Of these, 77 were males and 50 females. Under 5 years there were 28 cases (17 males and 11 females); from 5 to 10 years 29 cases (16 males and 13 females); and over 10 years 70 cases (44 males and 26 females). There were 26 deaths (or 20·39 per cent.), and 11 post mortems were performed.

Cerebro-spinal fluid.—In 51 cases lumbar puncture was carried out, and in 44 cases the cerebro-spinal fluid was examined. In 43 cases cytological reports were made. In 25 cases lymphocytes and in 4 cases leucocytes were found in excess. In 6 cases lymphocytes and in 2 cases leucocytes were in marked excess. Protein was present in excess in 26 cases. Organisms were found in 16 cases, no organisms in 12, Gram-negative organisms in 2, and Gram-positive in 2 cases.

History and mode of onset.—A history of injury to the head occurred in 9 cases, of tooth extraction in 2. There was a two-stage history in 46 cases, sudden onset of nervous symptoms without previous illness in 36, gradual onset of nervous symptoms in 17, whilst the onset was undetermined in 28.

General symptoms.—Sweating was marked in 13 cases, diarrhœa in 7, and constipation in 29 cases. Glycosuria occurred (without previous history of it) in 1 case, acetonuria in 4 cases. At the onset vomiting occurred in 38, pain in hypochondrium in 13 cases. *Rashes* occurred in 27 cases, erythematous in 12, miliarial in 2, petechial in 5, and herpes in 8 cases, and of these 6 were labial and 2 gluteal. Desquamation was observed in 2 cases, joint swelling in 2 cases, œdema of the legs in 1 case, enlargement of glands of head and neck in 1 case, and bedsores occurred in 1 case. Dental irregularities were not positively recorded in more than 10.

Signs and symptoms referable to nervous system: Mental.—Emotionalism or "hysteria" was marked in 5 cases. Mutism (apart from silence during drowsiness) was noted in 7 cases. Delirium was marked in 19, maniacal delirium noted in 2, "acute delirious mania" following "stupor" in 1, delusions or hallucinations (apart from delirium or mania) in 3 cases. Nocturnal sleeplessness with diurnal drowsiness was marked in 3 cases, "drowsiness" in 30, stupor or prolonged lethargy in 26, "unconsciousness" or

coma in 25, and sequential dementia in 5 cases. *Physical.*—Epileptiform fits or convulsions were present in 15 cases; tremors, twitching, or choreiform movements were marked in 22 cases, trismus was marked in 2, head retraction was marked in 23, and limb spasticity was marked in 29 cases. Paresis or paralysis of limbs (apart from general asthenia) occurring transitorily or otherwise without hypertonia was noted in 47 cases, atrophy of limb muscle groups (apart from generalised muscular atrophy) in 10, facial paralysis (other than transitory) in 8, amaurosis (partial or marked) with slight changes in papilla in 5, ptosis was marked and persistent in 23, strabismus occurred in 19, nystagmus in 14. Deafness and tinnitus were marked in 5, dysphagia occurred in 5, hypoglossal palsy was marked and persistent in 5, pain and tenderness in limbs were marked in 11, and formications, tinglings, and numbness were marked in 6. In 6 cases ascending paralysis occurred, and in one case (not included in the above statistics) trophic changes and gangrene of the finger-tips appeared, probably due to an acute ascending central myelitis.

A very careful inquiry had convinced him that the various Heine-Medin categories—paralytic, spasmodic, and psychical—had been known in Europe for many centuries. Their prevalences or recurrences (pandemic, epidemic, endemic, communal, or commensal) had invariably been associated, concurrently or coincidently, with wider but similar prevalences or occurrences of catarrhal, sudoral, or nervous fevers, now generally regarded as influenzal. The cases spoken of as "infantile paralysis" represented only one end of a spectrum.[2] The other end was represented by various forms of "encephalitis," including the "acute delirious mania" of Dr. Luther V. Bell.

Discussion.

Sir ARTHUR NEWSHOLME pointed out that diseases which might occur in conjunction with each other and under similar epidemiological conditions were not necessarily the same.

Lieutenant-Colonel GOODALL agreed with Dr. Hamer that this disease was the same as that described by Sydenham, who also called it "the new disease." The duty of pathologists, clinicians, and epidemiologists was to separate diseases. Diseases which were similar were not necessarily identical.

Dr. CROOKSHANK drew attention to the fact that "poliomyelitis" attacked a part of the organism which in children was in an early stage of development — namely, the anterior horn cells. This might be the reason why growing children developed flaccid atrophy in a manner which did not appear in grown-up people. The child grew and developed, whilst the anterior horn cells remained stationary.

Dr. F. BUZZARD said that encephalitis in children was more common than was generally recognised. He had seen two cases of encephalitis lethargica which at first sight appeared typical of paralysis agitans. If the mid-brain were attacked cases of the paralysis agitans class were produced.

Captain BOX said that he had seen a case of encephalitis lethargica in 1913, with typical clinical findings and post-mortem lesions as described by Colonel Mott. Out of 14 cases in which he had had cerebro-spinal fluid examined 6 showed excess of lymphocytes, 6 showed blood, and 2 were negative. In no case was the fluid under pressure. Two cases had rashes, pustular in one case and in the other like measles, but with a different distribution. There was one case of optic neuritis. In three cases there were false attitudes of the head, showing a deviation from one or other shoulder produced by some interference with the peduncular system.

Dr. J. A. MURRAY, Captain DA FANO, and Dr. H. INGLEBY also spoke.

SECTION OF SURGERY.

Spolia Opima.

A MEETING of this section was held on Oct. 23rd, when Sir JOHN BLAND-SUTTON delivered his Presidential address, in which he gave demonstrations of museum specimens. Speaking of abdominal surgery, he said that in many cases operation left the patient in a worse state than before. This also applied to gastric surgery, about which nothing had been learned since 1881, when surgeons took up the surgery of the stomach. Less than a hundred years ago simple gastric ulcer was confounded with carcinoma. Bilocular stomachs used to be of interest in the post-mortem room, or were a curiosity of the museum. When Darwin came on the scene they became of interest to anatomists and were regarded as a result of atavism. They were now known to be very common and the result of disease. He had operated on three cases in which the stomachs were joined by a very small isthmus. The isthmus was removed and the stomachs were joined, but the patients were unrelieved and gastrojejunostomy had to be performed. The contracting influence had apparently persisted after the operation. He gave a review of surgery since the time of Hunter, and described the amount of suffering supported by patients before the introduction of anæsthetics, and remarked upon the extraordinary skill and quickness of operations of the surgeons in those days.

SOCIÉTÉ DE BIOLOGIE, PARIS.

THE meeting of this society on Oct. 19th was the first of a series of inter-Allied gatherings devoted to the Biology of War. The subject chosen was Shock, and the following is a summary of some of the papers read:—

W. B. CANNON: The Origin of Traumatic Shock.

Le choc traumatique est caractérisé par pression artérielle basse persistante, pouls accéléré, paleur, sueurs, respiration superficielle rapide. Pression artérielle basse persistante n'est due ni à faiblesse cardiaque, ni à manque de tonus vaso-constricteur. Hyperglobulie dans les capillaires accentuée par le froid. Réduction de la réserve alcaline parfois assez forte pour déterminer l'acidose; elle est due à l'abaissement exagéré de la pression sanguine qui amène l'anoxhémie. Si là pression sanguine est demeurée basse longtemps, impossibilité de la relever: les cellules nerveuses étant très sensibles au manque prolongé d'oxygène. Le choc n'est pas du à perte du tonus vaso-constricteur, ni à une embolie d'origine graisseuse, ni à l'acapnie; il est donc du à l'effet du traumatisme tissulaire, c'est à dire origine toxique. En effet les phénomènes apparaissent quelques heures après la blessure, même quand les conductions nerveuses sont supprimées, n'ont pas lieu si l'on a soin de supprimer l'irrigation sanguine de la partie blessée, et ils se produisent si l'on rétablit le courant sanguin. Traitement: Rechauffer le sujet; relever pression artérielle; séparer du corps la région traumatisée par garrot ou résection.

QUENU: Shock as an Intoxication.

Le choc est une intoxication dont l'origine est dans la partie blessée; les phénomènes n'apparaissant que 5 à 6 heures après la blessure ne sont donc pas des phénomènes d'inhibition. Il y a résorption de produits toxiques. Quel est le poison? Dislocation de la molécule albuminoide? Poison chimique dans le sang? Observation: Soldat blessé au pied porte un garrot pendant 9 heures; à ce moment excellent état général. On enlève le garrot—trois heures après état de choc.

CANNON cited five similar cases.

PIERRE DELBET: Lessons from Experimental Shock.

Observation: Muscles broyés aseptiquement, injectés dans le péritoine: phénomène de choc. Primitivement, manifestation sur le système nerveux. Secondairement, accumulation des éléments figurés dans les capillaires, donc ralentissement de l'oxydation, modification de la cellule hépatique. Il faut opérer d'urgence le choqué, la thérapeutique pathogénique étant de supprimer le foyer toxique.

P. DUVAL and GRIGAUT: Nitrogen Retention in Wounded Men.

Il y a chez les blessés augmentation de l'azote résidant du sang. Cette rétention azotée est fonction du degré de désintégration azotée des tissus sous l'influence du traumatisme, ainsi que du degré d'altération de la cellule hépatique. C'est cette rétention qui atteignant certaines limites provoque les accidents toxiques du choc.

LOÜET: Injections of Camphor for Shock.

Particulièrement heureux chez les polyblessés, les blessés du segment inférieur, les thoraciques, ces résultats ont été encore plus satisfaisants chez les blessés traités précocement, c'est à dire dans les Postes de Secours. En paraissant voir dans le choc initial un phénomène inhibitoire l'auteur expose les conclusions d'ordre physiologique et chirurgical que ses recherches lui ont permis de préciser. Grâce aux injections intraveineuses d'huile camphrée le chirurgien pourra désormais intervenir plus tôt chez cette catégorie de grands blessés afin d'éviter des graves complications secondaires toxiques ou septiques. Le Médecin Major Loüet demande que l'injection intraveineuse d'huile camphrée soit systématiquement pratiquée dans tous les Postes de Secours divisionnaires ainsi que le garrot (indications Cannon), la transfusion sanguine (méthode Jean Brau).

CL. VINCENT: Causes Predisposing to Shock.

L'homme qui se bat perd son tonus. Observation: Après 12 jours de bataille, sur 22 hommes, 14 ont une pression artérielle maximum inférieure à 12. Après deux jours de repos, sur 9 hommes, 6 ont une pression maxima inférieure à 12. Un soldat atteint de néphrite à une pression maxima inférieure à 8. L'homme qui se bat est un hypotendu.

GOVAERTS and ZUNZ: Conditions of Circulatory Collapse.

1. Collapsus post-hémorragique: diminution d'hémoglobine, de globules rouge, de la viscosité. Pression artérielle basse, pression veineuse considérable. 2. Collapsus infectieux: chute de la pression, augmentation de globules rouge, d'hémoglobine, de la viscosité, pression veineuse faible. 3. Collapsus ciseul; traumatique; pas de modification du nombre de globules rouge, du taux de l'hémoglobine, ni de la viscosité, pas de chute considérable de la pression artérielle.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 2, 1918.

The Influenza Epidemic.

DURING the week the epidemic of influenza, if it has abated in some localities has broken out in others, and on all hands the seriousness of the visitation is being felt. The restraint practised by the daily press in regard to public matters has not survived the temptation to paint this visitation in the tints of the 12 plagues of Egypt, in comparison with which any account of our actual knowledge must appear colourless. In Paris a rumour of cholera arose out of a series of cases with broncho-pneumonia which proved rapidly fatal with general cyanosis, but the Paris rumour is little more lurid than the stories prevalent in London. A natural desire to blame somebody has resulted in an attack upon the Local Government Board for having failed to arrest the development of the epidemic. Furthermore, it is suggested that had a Ministry of Health been in existence there would have been no epidemic at the present time, or, at least, it would never have been allowed to develop. We are in entire accord with those who desire the formation of a Ministry of Health, but we deprecate regarding it as a panacea for all epidemic evils. In the *Times* of Oct. 23rd it is stated that "influenza was very prevalent last summer, and had the experience of the eighties been called to mind it would have been evident that a summer epidemic was likely to be followed by a winter one of greater severity." With this statement we cannot agree. It is contradicted by the Registrar-General's records, which show that summer epidemics are unusual, and that the occurrence of an epidemic of influenza followed by an even more severe epidemic of the same disease within three months is almost unknown. In the 26th, 27th, 28th, 29th, and 30th weeks of this year the deaths from influenza registered in London were respectively 67, 218, 287, 192, and 86; in the 39th, 40th, 41st, and 42nd weeks the corresponding figures were 17, 17, 80, and 371. The experience of all previous epidemics in London is that excessive mortality from influenza in any single epidemic does not continue beyond a period of about six weeks. If this holds good in the present instance we may hope that the excessive mortality caused by the present epidemic will soon begin to decline. There were, however, 1256 deaths in London attributed to influenza in the week ending Saturday last, Oct. 26th.

The experience of London is in large measure that of the rest of the country. It has to be borne in mind that the conditions of living are just now abnormal. The people are suffering from an unusual strain, both mental and physical. Many persons unaccustomed to hard work are engaged in laborious tasks in munition factories and the like; women have replaced men in sundry arduous occupations; few families are without one or more of their members fighting in the deadly struggle on the battlefields of Europe or the Near East, and some, indeed, have already lost their nearest and dearest. Food conditions, too, are difficult, and some persons may be suffering from the effects of overwork and under-nourishment, although, as a matter of fact, the nation in these respects is coming wonderfully well through the ordeal. But circumstances in a proportion of instances have led to lowered vitality and weakened resistance to disease. The reduction of the railway services, as also of trams and omnibuses, has led to overcrowding of all public conveyances when people are going to, or returning from, their work, thus affording very favourable opportunities for diffusing an infection like that of influenza, which is given off by the lungs and naso-pharyngeal secretions in the form of droplets expelled in the act of coughing or sneezing. Persons in the early stage of an attack and healthy carriers are able to infect their fellow travellers unknown to themselves or their victims. Hopeful evidence is accumulating that this infection only takes place at quite short range. A miniature epidemic in a surgical ward graphically recorded by Major MICHAEL G. FOSTER and Major H. A. COOKSON in another column suggests that trifling barriers may limit the spread of influenza. Professor VINCENT puts his attendants at the Val-de-Grâce in Paris in masks, covering eyes as well as nose and mouth, since in his view, although the range is short, lacrymal infection is a frequent occurrence. Theatres, music-halls, and especially picture palaces, often overcrowded and ill-ventilated, give great facilities for the spread of infection at closest range. These are the obvious contributing factors to the spread of the epidemic, and while they must be as well known to the public as to the medical profession, we cannot see on the part of the public any general attempt to limit intercourse where this is possible. To congregate and brood is too much the public attitude. In France, we learn from our Paris correspondent, the conditions are in the main the same as with us. The epidemic flared up with the onset of cold weather and the normal death-rate in Paris has been doubled. In Lyons all the schools and most of the theatres and cinemas are closed, while in Paris itself a wise caution has resulted in the postponement of a great sportive manifestation in which 10,000 young people were to take part. The Paris prefecture has obtained the compulsory notification of cases of influenza, which is not on the list as drawn up by the Academy; disinfection of rooms after fatal cases is also being carried out by the police authority. The department of military hygiene has organised a special service for influenza cases, which are being isolated in the military hospitals. Research is not being neglected and Dr. NICOLLE, director of the Pasteur Institute at Tunis, has announced to the Academy of Sciences his discovery of the pathogenic agent in the form of a filtrable virus, from which he hopes to prepare a serum.

Knowing all that we do, it is well to admit frankly that we are as yet in ignorance of the most important thing of all—namely, the actual conditions which cause the influenza virus from time

to time to take on increased virulence. It is possible that the exceptional conditions resulting from the war may have exercised some influence in this direction. The infection has this year been carried from one continent to another by shipping; most of the armies in the field have recently experienced the effects of epidemic influenza in more or less degree. In Europe, Spain seems to have been the country first attacked, hence the present term "Spanish influenza" for what was on a former occasion called "Russian influenza"; and subsequently Portugal, France, Holland, Germany, Austria, Hungary, Russia, Italy, Switzerland, Sweden, Norway, and Denmark were invaded. Influenza has been severely epidemic in South and West Africa; it has committed serious ravages in India, especially in Bombay; it has spread to Australia, South America, the West Indies, Canada, and the United States. The problem of how to limit the spread when it has gained a hold upon the country is a very difficult one, and the difficulty has been much increased by the shortage of medical men, which has placed the National Service Ministry in the awkward position of choosing between the needs of the fighting front, which are very urgent in view of the continued lamentable loss of doctors from wounds, and those of the home front, where many have been put out of action by influenza. Sir AUCKLAND GEDDES'S assurance is, therefore, doubly welcome that he has released for whole-time civilian practice in needy districts a very large number of medical men who were in official employment. For the rest we may trust the Local Government Board and the local health authorities to do their best in the circumstances, but the work of prevention is largely dependent upon the people themselves. If those who feel ill would stay at home; if those who are well would avoid travelling in railway carriages with the windows closed or in unventilated trams and 'buses; and, above all, if the public would forego picture palaces or other crowded places of amusement so long as the epidemic continues, much would be done to limit the spread in populous centres.

Medical Practice in the Light of the Whitley Report.

THE Conference of Local Medical and Panel Committees held last week at the Connaught Rooms in London signalised the end of what may be called a party truce. Six months ago the Conference decided by an overwhelming majority not to embarrass the Government at a time of great national stress by pressing their just claim for an increased capitation allowance under the National Insurance Act. On Thursday of last week a vote on the same proposition was lost by a majority of less than two to one, many of the keen medical politicians present regarding the time as fitting for a great push. Gentler counsels, however, prevailed on the representation of the Insurance Acts Committee that no immediate action could be obtained without the proclamation of a general strike, for which an 80 per cent. vote of panel practitioners would be required. This would put a premature end to the conversations now taking place with the Commissioners in regard to compensation for increased cost of insurance practice arising from war conditions and other concessions short of alteration of the capitation fee itself. These conversations appear to be a realisation in matters medical of the trade council, which is the main theme of the Whitley Report; and although the Conference by its vote of confidence in the Insurance Acts Committee ratified this important principle of pourparlers at the source between employers and employed, feeling ran very high, just as in labour circles, against local approaches between panel (medical) and insurance (lay) committees, two London delegates alone supporting such local overtures. In certain towns, however, experience has already shown the beneficial effect of action of this kind, which is in harmony with the few successful adventures in industrial coöperation. Even the hot-heads agreed that an 80 per cent. strike among the rank and file of panel practitioners was unattainable in their own areas, with the possible exception of Lancashire.

Feeling at the Conference was unanimously against obtaining from the Insurance Commissioners differential distribution of pooled funds as between urban and rural practice, or different conditions of urban practice. Although the pressure of work without correspondingly increased pay has been keenly felt in some munitions areas, no one desired to introduce a possible source of dissension in the form of competition for a larger proportion of the central pool. The general principles for a more rapid and equitable distribution of the central pool formed the subject of an interim report which gained the assent of the Conference, and we print on p. 601 an outline of these principles, which will be considered in detail by Panel Committees throughout the country before their final acceptance. But it was admitted without question that existing conditions press with peculiar hardness upon rural practitioners. The mileage allowance at present granted does little more than cover the increased cost of petrol, if that; and in certain flagrant cases quoted the rural practitioner pays money for the privilege of making distant visits. A request for an increased allowance on account of mileage and for an addition on account of "timeage" was pressed upon the consideration of the Commissioners.

It is not unfair to conclude from the voting at the Conference that the financial conditions of Insurance practice are not very distasteful to a large majority of doctors on the panels. A further application of the principles of the Whitley report to panel practice might make these conditions positively agreeable, and this lesson is pointedly drawn in Professor H. R. KENWOOD'S presidential address to the Society of Medical Officers of Health, a portion of which we print on page 599. Professor KENWOOD foresees that the general practitioner will come to realise the need for working on preventive lines in connexion with disease of all kinds, and will in so doing take over much of the clinical work at present in the hands of the public health service. A health officer himself, he entirely disclaims the threatened encroachment by the official Public Health Service upon the domain of the general practitioner. To him this is a possible but an undesirable eventuality. The arbitrary and narrow distinction between preventive and curative medicine is breaking down, and the closer local organisation of administrative and clinical effort affords a pleasing alternative to a full-blown rate- and State-aided medical service. This can only come about by greater scope of work on the part of general practitioners upon councils of local sanitary authorities, activating these authorities by their presence to a fuller and sounder health policy. This is the true Whitley principle.

Annotations.

"Ne quid nimis."

DISPENSARY SUPERVISION OF TUBERCULOSIS IN THE HOME.

THE administrative control of tuberculosis is a problem deserving more than all the attention which is being given to it. Dispensary supervision is one of the simpler methods at present in use, and we would direct attention to Dr. George Jessel's article in the last issue of THE LANCET, in which he suggests that by suitable instruction, close supervision, and the occasional help of care committees some reasonable degree of sanatorium practice can be obtained from the systematic dispensary supervision of tuberculous patients in their own homes. His conclusion is that such home treatment is both "possible and safe" in dealing with 70 per cent. of the cases occurring in an industrial area of Lancashire. This proportion of the families concerned is able to provide a separate bedroom for the tuberculous member. It will readily be agreed that from home treatment under close supervision a considerable measure of success is obtainable with suitable patients in suitable homes in suitable districts. But it is always difficult to secure the proper regimen (including rest and exercise) and the necessary direction and supervision of details. The medical officer is dependent upon the intelligence and goodwill of the patient in carrying out instructions which cannot be enforced, and entirely suitable patients and conditions for home treatment may be regarded as exceptional among the poorer classes. We think that if the supervisory and stimulating visits of the medical officer and nurse or health visitor are not more frequent than those indicated by Dr. Jessel, the care of details will have a tendency to relax as the disease progresses, at a time when the need for such care is steadily increasing. A few months of previous training in a sanatorium and, when necessary and practicable, the provision of a shelter will certainly contribute materially to the number of instances in which home treatment becomes "possible and safe." It is to be hoped that Dr. Jessel will be able to develop his thesis further, and more particularly in the direction of a careful study and record of the course of the disease among his home-treated patients.

THE CONTROL OF UNDESIRABLE IMMIGRANTS IN THE UNITED STATES OF AMERICA.

THE methods of preventing the introduction of epidemic disease at the Port of London were dealt with recently by the medical officer in a lecture at the Royal Institute of Public Health which we summarise on p. 612. Similar measures are in force in the United States of America. In 1912 quarantine authorities situated at the more important U.S. Atlantic ports examined 34,000 specimens of fæces from ship passengers and crews coming from cholera-infected ports. At the New York quarantine the cholera vibrio was isolated from 28 persons sick with the disease and from 27 healthy persons. Seven cases of cholera were detected at other ports by the same methods and the disease was kept out of the country. During the cholera epidemic in Germany of 1892–93 the American authorities instituted an inspection on foreign soil of everything to be imported to the United States. Officers of the United States Public Health Service stationed at foreign ports supervised the water- and food-supply of departing vessels, as well as inspecting crew and passengers. Those coming from infected localities were detained under observation for five days before being permitted to embark. In the Philippines, since American occupation, the inter-island spread of cholera, which in the past took toll of so many lives, is checked by a careful sanitary supervision of vessels at ports of departure and arrival. Extraordinary measures were taken a few years earlier to prevent the importation of bubonic plague. Under the direction of the U.S. Surgeon-General Pacific ports, notably San Francisco, were "cleaned up"; the community was freed of rats by a "drive" that necessitated the employment of scores of inspectors and which overlooked hardly a square foot of the city; the coöperation of the populace was secured by explaining the danger to them through meetings at schools, workshops, and offices and the daily press; quarantine precautions were increased. The plague was kept out. The public hygienic activities in the United States are not concentrated in the hands of one sanitary bureau. Some of the public health branches are a part of the U.S. Department of Agriculture, others are in the Department of Commerce, and the most important, the Public Health Service, is affiliated to the Treasury Department. One of its functions is the administration of the national maritime quarantine and the medical inspection of immigrants. It also makes special investigations of infectious diseases in States when necessary, although each several State has its own department of health. A large proportion of all persons engaged in public health work, both official and voluntary, are members of the American Public Health Association, which, while not an official organisation, contributes through its journal and regular meetings towards the general policy of dealing with contagious diseases.

SCARLET FEVER IN JOHANNESBURG.

THE recent report of the acting medical officer of health of Johannesburg discusses the undue prevalence of scarlet fever in that city since October, 1917. The number of cases notified and the number admitted to the Fever Hospital during the last two years are as follows:—

Period.	Total number of cases.	Number admitted to hospital.	Cost.
Year 1916-17	213	27	£516 per annum.
,, 1917-18	2083	440	£8408 ,,
Month of July, 1918	255	47	£759 for the month.

The epidemic decreased somewhat between February and April of this year with a rise again in June. In July the cases fell to 255, and during the first 20 days of August only 126 cases were notified, showing a distinct tendency to decline of the epidemic. The problem of isolation became a perplexing one. The Johannesburg Nursing Home was opened at the beginning of July as an overflow for convalescent cases of scarlet fever, but soon after it was opened a cross-infection of scarlet fever and measles occurred both at the Fever Hospital and at the Nursing Home. So that fresh cases of scarlet fever could be admitted to neither. In consequence it again became impossible to isolate a considerable

number of cases of scarlet fever in which home isolation was entirely unsatisfactory. The Hospital Board thereupon decided to provide additional fever accommodation at the Otto Beit Convalescent Home. In addition to this general measures have been set in action, including the posting of circulars (in two languages) in public conveyances, the disinfection of tram cars, and the issue of special instructions to school authorities and to sanitary inspectors.

TRAINING FOR INFANT WELFARE WORK IN INDIA.

EVERYONE will welcome with satisfaction the establishment of a school for the training of women health visitors and maternity supervisors by a voluntary association at Delhi, where the pupils will live under the supervision of the municipal health visitors. The conditions of entry are stringent. The candidate must be over 21 years of age, must have passed the sixth standard of general education or its equivalent, and must possess a certificate in midwifery approved by the council of the school. Preference will be given to candidates with a previous training in general nursing. Applicants, besides a good acquaintance with English, must know at least one Indian vernacular, and produce satisfactory evidence of physical and moral health. The course extends over six months, beginning on Nov. 1st, with the first month on probation. Pupils successful at the terminal qualifying examination will receive diplomas as trained health and maternity supervisors. The course will be made up of—

(*a*) Lectures on physiology, hygiene, and domestic sanitation, general and tropical sanitation, general medicine, tropical medicine, diseases of children, infant welfare, pre-maternity work.

(*b*) Practical demonstrations on general sanitation, domestic sanitation, and childbirth, first-aid and home nursing, with special reference to children's ailments.

(*c*) Lantern lectures and talks to mothers.

Pupils unable to pay their own expenses will receive a monthly stipend of Rs.40, enabling them to be trained, on the stipulation that they then serve the association for a period of three years. A monthly salary of Rs.100 and furnished quarters are guaranteed to them during this period. The salaries paid to maternity supervisors are on a rising scale, reaching at least Rs.250 a month. The initiative set by Delhi is one which might with advantage be followed by the innumerable other populous centres of India.

THE SEROLOGICAL LOCALISATION OF ORGANIC BRAIN TUMOURS.

Dr. J. M. Retinger records in the *Archives of Internal Medicine* for August some interesting results gained in localising gross brain lesions by using a slightly modified form of the dialysis method of Abderhalden for testing the blood serum. Of the cases in which this method was used, 25 had been sufficiently studied clinically, or verified by operation or necropsy, to be considered. The clinical diagnosis or symptoms were not known to the writer, who performed the serological tests in most of the cases. On the basis of the findings in this limited series of cases, the serological diagnosis was supported in four instances by post-mortem results, in two by operation, and in 15 tests were found to be in complete agreement with definite clinical evidence. Two cases differed from the clinical diagnosis, but the latter had not been controlled by necropsy or operation, and in one case the necropsy proved the test to be erroneous. These results seem promising. The principles of this serological method of testing are familiar. It is found that pathological processes, or even physiological processes as in pregnancy, occurring in organs may release into the blood stream ferments found to possess a specific digestive faculty for such organs; this faculty can be tested by the power of such serum to digest "substrates" of the particular organ suspected, obtained and estimated under delicate laboratory conditions. In these tests the substrates used were obtained from human brains from necropsies of normal people. All the large vessels were removed, and in the cortex only the grey matter was used. The pieces were cut into small particles the size of a pea and thoroughly treated to remove all blood, fat, and lipoids. Each substrate was labelled according to the site from whence it was obtained. Against these various substrates the serum of the patient was tested, the presence of its digestive power, as determined by the ninhydrin colour test upon any particular substrate, indicating the probable involvement of the same area in the patient as that from which such substrate was obtained. A brief résumé of the cases examined is given. Case 10 is an interesting instance. Thirty-four different substrates were used. The motor area in the cortex showed pronounced positive reactions. The pituitary also gave strong reactions. The lesion lies in the anterior lobe of the pituitary. Diagnosis: acromegaly with occasional epileptiform attacks. Case 18 is also instructive. Forty substrates used. Lesion not in cortex. Most pronounced reaction with the cerebellar grey matter, dentate nucleus, anterior pituitary, and corpus callosum. The final diagnosis was a lesion of the cerebellum, confirmed on operation. Many of the other examples given are equally convincing, suggesting that, in some hands at any rate, the method may come to possess a more than academic value.

PERFORATING ULCER OF THE HARD PALATE IN VINCENT'S DISEASE.

THE form of ulcerative tonsillitis associated with a spirochæte and a fusiform bacillus, known as "Vincent's angina,"[1] has recently attracted attention because of outbreaks at the front described as "trench mouth," "trench throat," and "trench gums" associated with the same organisms. It is also known that ulcerative lesions associated with these organisms may occur in other places—the bronchi, gastro-intestinal tract, and genitals. In the *Journal of the American Medical Association* Dr. L. F. Barker and Dr. R. Miller have reported a case of ulcer of the hard palate due to the same cause.

A man, aged 47 years, noticed one day on the roof of the mouth a small white spot, which developed in a few days into an ulcer that gradually became larger and more painful. Despite a negative history, syphilis was suggested by several practitioners. On examination there were marked oral sepsis and gingivitis, especially round the posterior molars, a fœtid odour of the breath, and a punched-out ulcer of the size of a dime on the hard palate, covered with thick, creamy, easily removed exudate, and surrounded by a deep red, somewhat indurated areola. The base of the ulcer bled easily. The clinical picture certainly suggested syphilis, a view concurred in by a throat specialist, but the Wassermann reaction was negative. Smears from the exudate showed enormous numbers of the *B. fusiformis* and many coarse, readily stained spirochætes, with from five to eight undulations. Vincent's angina was diagnosed and the lesion healed in a few days under dichloramine-T and local application of arsphenamine solution.

[1] THE LANCET, 1905, i., 1260.

The term "Vincent's angina" generally means a form of ulcerative tonsillitis due to the associated organisms mentioned and is the commonest form of this infection, but the term "angina" is obviously inapplicable to ulcers due to the same cause in other parts. Dr. Barker and Dr. Miller therefore suggest that the term "Vincent's disease" be applied to the whole group. Vincent's angina is liable to be confounded with syphilis and diphtheria. Hence the importance of bacteriological examination.

PUBLIC HEALTH REFORM IN EGYPT.

A YEAR ago the High Commissioner of Egypt sanctioned the appointment of a Commission to study the reforms necessary for efficient public health administration. This Commission was formally approved by the Council of Ministers in June last and consisted of Lieutenant-Colonel Andrew Balfour, R.A.M.C., formerly Principal of the Gordon Research Laboratory at Khartoum, president; Lieutenant-Colonel G. E. F. Stammers, Mr. E. S. Crispin, Director of the Sudan Medical Department, and Dr. C. Todd, Director of Laboratories, Public Health Department. Its mandate was to examine the organisation and duties of an Egyptian Department of Public Health and its relations to other services; to submit proposals broadening the sphere of action of the existing Department, and to suggest the number and nature of the posts which will be necessary for the proper working of the Department without, however, nominating or making recommendations regarding them. After frequent meetings and a series of inspections into representative public health institutions, the Commission has drawn up a Report proposing reforms of a far-reaching character. The Report has not been published yet in this country but has now appeared in the *Egyptian Gazette*. Its more salient features will be commented upon here in an early issue, and we take this opportunity of recording our sense of the prescience shown by Sir Reginald Wingate, the High Commissoner, in appointing the Commission. For now is the right moment for setting in motion the outspoken recommendations of the Balfour Report.

THE diploma of honorary Fellowship of the Royal Society of Medicine will be presented to Sir Alfred Keogh at a special meeting of the Fellows on Wednesday, Nov. 13th, at 4.30 P.M.

THE Bradshaw Lecture of the Royal College of Surgeons of England will be delivered at the College on Thursday, Nov. 14th, at 5 P.M. Lieutenant-Colonel D'Arcy Power, the lecturer, has chosen as his subject Cancer of the Tongue.

FROM the Department of the Controller of Coal Mines we learn that a claim for additional fuel allowance on the ground of illness in childbirth will be allowed, the maximum quantity of fuel granted on such a claim being 5 tons.

AT the Royal College of Physicians of London Dr. F. H. Teale will deliver the Horace Dobell lecture dealing with Bacterial Toxins on Tuesday next, Nov. 5th. On the following Thursday, Nov. 7th, Colonel W. Aldren Turner, A.M.S., will give the Bradshaw lecture on the Neuroses and Psychoses of War. The Fitz-Patrick lectures follow on Nov. 12th and 14th, Dr. Arnold Chaplin having chosen for his subject Medicine in England during the Reign of George III. The hour in each case is 5 P.M.

MEDICAL RECONSTRUCTION:

THE SOCIETY OF MEDICAL OFFICERS OF HEALTH AND THE PUBLIC HEALTH SERVICE.

The Ministry of Health Bill and the Relation of the General Practitioner to the Public Health Service

AT the end of his Presidential Address upon the reconstruction of the Society of Medical Officers of Health, Professor H. R. KENWOOD made the following references to the Ministry of Health Bill and the relation of the general practitioner to the Public Health Service.

The Ministry of Health.

So many exaggerations of what a Ministry of Health can readily achieve have emanated from well-meaning enthusiasts with no first-hand acquaintance with health problems in their social setting that the Ministry must prove disappointing to many; but it will satisfy no one unless care is taken to start it upon the right lines. The difficult problem which lies before the Ministry of Health is well expressed in a letter by "Salus" in the *Times* of Sept. 26th, 1918. Therein it is pointed out that "successive Governments have never realised the mischief involved in our inveterate habit of piecemeal legislation, hand-to-mouth attempts to tackle by successive bites particular parts of what is essentially one problem and ought to be regarded and handled as one problem. ..... The problem of making proper provision for attaining and maintaining the maximum health of the people is broken up disastrously into many disconnected parts. All these different parts ought to be closely interconnected, planned, and worked in the closest relation to one another as coördinated parts of one system one whole."

The staffs of certain central Departments engaged in health work are to be transferred to the Ministry. This is, of course, necessary and desirable, but if they are merely to continue their operations under one roof (as it were) instead of several it is difficult to see where the value of this concentration will come in to compensate for all the disturbance it entails unless the Bill affords *a guarantee that the field of public health shall be viewed and dealt with as a whole* and not in separate "watertight" compartments, as hitherto. The fact is indisputable that central Government Departments have in the past done very little indeed to initiate public health reforms or to prepare public opinion for them. These Departments were never better medically advised than to-day, but it is too much to hope that Government action in public health matters will cease to follow, at an unnecessary distance, public opinion and local action. Indeed, the Departmental attitude of mind seems to be too groovy, too hesitating, and too compromising to originate advice and to initiate action. Take the Ministry of Health itself. The idea of this originated outside the Government or of any of its Departments; it owes its conception mainly to dissatisfaction of Government methods; the very impulse that is leading to its establishment is, again, external; and, furthermore, the impulse that will guide the Ministry to fresh conceptions and a bold initiative will also have to be external. It is because I realise that if this Bill is to be a real step on the road to an effective health policy that will not be unduly narrowed by the Departmental outlook, that I would urge the necessity of laying a sound foundation to the Ministry by doing what is possible to guard against this. It seems to me that the danger is great.

Need of Surveying the Problem of National Health as a Whole.

As an instance of compromise—and herein lies the main danger to which I would direct attention—the Bill, as publicly announced, provides for several consultative councils, each of which will doubtless play its own independent hand, and no linking-up advisory council is mentioned which shall be representative of the whole field of public health, and strengthened by a fair representation of non-official expert opinion, in order to bring a broader, fresher, and bolder outlook to bear upon the problems to be faced. Assuming that one of the proposed councils is to be a purely medical council, the real solution of public health problems involves manifold considerations; it is never entirely medical, although medical guidance must be predominant. I suppose that another council will deal with National Health Insurance. Well, the scheme of National

Health Insurance is capable of being made a very useful measure of public health, to which I question whether it has hitherto contributed to any material extent; but will this be as likely to take form at the hands of a special council, advising the Minister departmentally, as if it were represented on a general advisory council, leavened by those who are capable of stimulating the development, improvement, and adaptation of the scheme to the general and comprehensive public health needs?

At a meeting of members of the medical profession held at Steinway Hall on Oct. 1st Dr. Addison, Minister of Reconstruction, expressed the opinion that, as a first step, it was necessary to bring together the assortment of different Departmental responsibilities in health matters, and to secure that the thinking out and development of a systematic health policy, commensurate with urgent national needs, should be made the duty and responsibility of *a definite body of men*.[1] He stated that we should and must be the victims of sporadic, disjointed, and often conflicting effort until this was done. Is it likely, I would ask, that a Central Authority to coördinate all the public health work of several Central Departments, to take a comprehensive survey of public health needs, and to make far-reaching provisions for these, can be as competently advised in its general policy by several independent councils? Cannot the Ministry at its very inception do something to detach itself from the departmental outlook and tradition? Whatever councils may be provided to deal with different branches of work cognate to the public health, surely one body with the task of comprehensively surveying the problem of national health as a whole, and with the duty of advising a strong Minister of the necessary fresh efforts and reforms, is *indispensable to the Ministry in the shaping of its broad policy*. Everything will depend upon how the Ministry is advised, and I am sure that the well-wishers of the proposed Ministry will be left cold and disappointed if the Government fails fully to respond to the general demand for a newer and broader outlook and a better coördination in public health matters.

Relation of the General Practitioner to the Public Health Service.

We are ever rising to higher ideals of what "Public Health" should mean. We now recognise it to embrace all efforts towards the uplifting of the people to higher levels of health, happiness, and efficiency. This can only be attained by better and fuller measures of education, organisation, and administration.

I suppose that it is due to the somewhat narrow lines on which we train for our qualifying diplomas and degrees (whether of Public Health or Medicine) that most of us health officers start our public work with insufficient appreciation of the very important part which the general practitioners of medicine, surgery, and midwifery play in public health; how mutually dependent we are for results; and how much the public health needs a clearer linking-up and a better appreciation of our related services. We may rest assured that the near future is going to secure this by better provisions for the curative branch of public health and, perhaps, a wider administrative control of it.

Our official public health work is regarded by many as encroaching more and more upon the domain of the general practitioner. Even Sir Clifford Allbutt has recently gone so far as to suggest that general practice may become but a gleaning after the reapers. I do not conceive that the trend of the future developments is towards this undesirable eventuality. It seems to me to be more in the direction of improving the value and status of the general practitioner by calling for a development of the preventive side of his duties, and by securing (with the assistance of rate- and State-aided support) enhanced facilities for better and more prompt diagnosis and treatment; and, therefore, rather than the scope of the work of the general practitioner becoming more restricted, it seems to be destined for a real and important expansion.

Surely the most valuable part of public health work lies to the hand of the general practitioner; and it is to his interest to broaden his views to a fuller realisation of this, and to see that he is well prepared to play his part in the service of the public health. May I develop this point a little further? There is a general disposition to make an arbitrary and narrow distinction between preventive and curative medicine; but the sphere of prevention is common to both and embraces everything that contributes to health. The major part of all disease is not, in our present social circumstances, preventable. Even the M.O.H. has illnesses which could have been prevented, and he often prematurely dies from one of them. In this large field of, at present, unpreventable or unprevented disease the general practitioner operates. It is mainly by his efforts that it can be reduced to minimum dimensions and an enormous wastage from disablement and premature death be avoided; for the mortality from the diseases that a local health authority with the most comprehensive provisions takes under its administrative purview barely relates to one-third of the premature deaths from all causes in England and Wales. And we must not underestimate the great part which the general practitioner plays in the reduction of disease that *is* recognised as preventable, for the prompt diagnosis and treatment of *all* diseases are essentially preventive measures, and we are dependent on him for that early diagnosis and notification of communicable disease which starts our repressive machinery and determines its value.

Suggestions in regard to the Improvement of National Health.

The general practitioner, more fully trained and better equipped with local facilities for diagnosis and treatment, and stimulated by a fuller public recognition of the need for and value of his services in the prevention, the early detection, and the prompt cure of disease, becomes the very cornerstone of the public health edifice. In the reduction of preventable disease he works with a very fine-meshed sieve, in comparison with which ours is coarse indeed. A Ministry of Health that can view the entire health problem as a whole will inevitably bring the general practitioner into a more intimately organised relationship with the general health policy. But before the best results can be obtained the general practitioner must be better equipped by according to preventive medicine a more prominent place in his training; for this is essential to the sympathetic and purposeful organisation of the curative and preventive branches of medical work that is destined to become established. He will then better realise the necessity of working more on preventive lines in connexion with all disease; he will also undertake much of the clinical work which, largely by his default, is now in the hands of public health medical officials; his status and public value will thereby be enhanced, and he will more generally serve upon the councils of the local sanitary authorities and assist his official colleagues in activating these bodies to a full and sound health policy. The general practitioner has also to be trained in reference to the social setting of his work, for to be effective he must know intimately the social life of his patients at home and at work. No sufficient instruction is given in these matters at any medical school, and yet the prime aim and duty of medicine should be to secure and conserve the healthy body *in all circumstances*. To quote Sir George Newman: "His ignorance of his relationship to the community and his detachment from the social evolution proceeding around him has been a substantial contribution to his great hurt and undoing as a practitioner, and has not seldom shut him out from a large and liberal education in medicine." In default of this awakening I believe that the ultimate remedy will have to be a rate- and State-aided medical service for those who stand in need of it—for the present unsatisfactory medical care of the poor (generally speaking) is too profligate in its wastefulness to be tolerated much longer.

Surely the great public health needs at the present day are: (*a*) for a more determined effort to reduce the prevailing ignorance and carelessness among the poorer section of the community in matters connected with their health; and (*b*) for improved provisions for the medical care of the poor. The public must rise more to the demands of their health needs; short of this, there is no real remedy. Shall we ever live to see, even in this age of strikes, the industrial workers organising a strike against unsatisfactory health circumstances? Among the poorer section of the community the preventable loss of health, the utterly inadequate provision for promptly restoring the sick, and the premature mortality that results are a national reproach. The reproach is felt. Politicians allude to it and are ever voicing the policy of "Salus populi, suprema lex," but they afford little evidence of the necessary vision and determination to adopt the fuller measures necessary to give effect to this policy. Unless we

[1] THE LANCET, Oct. 5th, p. 465.

tinker with the problem the pecuniary cost entailed will be more than compensated by the increase in our national efficiency and productiveness.

The difficult and often demoralising sanitary circumstances of the poor must be made easier and more stimulating to hygienic observances, and hence a reasonable standard of decent housing should be everywhere demanded by the Government. But the best treatment of disease must be provided by fully competent general practitioners and specialists and by greatly increased institutional provisions, free of cost whenever a person's pecuniary means cannot secure these.

Gentlemen, our broader and ever-broadening concepts of public health are expanding the domain of our work and interests. There is going to be a closer organisation of administrative and clinical effort in State medicine, and those of us who are administrative officials are not going to show any lack of sympathetic appreciation and support to any suggestions for promoting the greater part which the practitioner of medicine is destined to perform in the fuller work of public health.

INSURANCE PRACTICE.

THE DISTRIBUTION OF THE CENTRAL POOL.

THE Insurance Acts Committee in connexion with the British Medical Association presented to the recent Conference of Local Medical and Panel Committees an interim report on the method of calculating the remuneration of doctors under the National Insurance (Health) Acts. The scheme, upon which we comment in a leading article this week, is set out in the following outline :—

1. The central pool for the year would be actuarially fixed before the beginning of the year on the basis of the sale of insurance stamps, allowance being made for the natural increase of population, and all other relevant data being taken into consideration.
2. The greater part of this pool (say perhaps 95 per cent.) would be assigned to the various insurance areas in such proportions as might be fixed by an appropriate Committee assisted by experts, on the basis of the number of names of insured persons on the register of the area in the previous year, or on an average for previous years, the fractional assignment so arrived at being either for one year or for a short period of years.
3. The reserved part of the central pool (say 5 per cent.) would be used to increase the amount assigned to any particular areas which, in the course of the year, showed to the satisfaction of the Committee that there had been therein an altogether abnormal net increase in the number of insured persons. Any residue of this reserved sum could be distributed at the end of the year in the proportions agreed upon for the main amount, or, if preferred, could be carried forward.
4. The present temporary resident calculations would be done away with, as affecting distribution of the central pool, the numbers of such residents treated in areas in which they had an appreciable effect being taken into consideration in fixing the fraction of the central pool to be assigned to the areas.
5. In the absence of any indication to the contrary, the present practice of distribution to areas on a uniform basis would be followed; but, if the profession indicated a strong preference therefor, it might be possible to arrange an assignment to areas on a differential basis, differences in the incidence of sickness and in the conditions of practice in rural, colliery, industrial, urban, and residential urban areas being taken into account, but it is doubtful whether there are at present available data which would enable this to be done.
6. The area pool (with the exception of the small residue) being thus fixed at the beginning of the year, the distribution to individual practitioners would be made definitely quarter by quarter.
7. The basis of such distribution to practitioners within the area would be left, within wide limits, to local option, but would be in accordance with principles, methods, or conditions to be discussed in a further report on this part of the subject.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC.—In consequence of the prevalence of influenza the celebration of Founders' Day at the National Hospital for the Paralysed and Epileptic, Queen-square, W.C., arranged for Nov. 4th, has been postponed

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

THE following letter (enclosing a draft for £20) has been received by the hon. treasurer to the Fund :—

2, Beach-street, Clovelly, Sydney, Australia,
Sept. 6th, 1918.

Hon. Treas., Belgian Doctors' Relief Fund.

DEAR SIR,—I am enclosing a cheque for £20 (or rather draft) as a small subscription to the above Fund.

I have returned after three years of war, and know something of what these brave Belgian people must be living through.

Yours sincerely,
ROY WINN, M.B., Ch.M.

SUBSCRIPTIONS TO THE SECOND APPEAL.

The following subscriptions have been received up to Monday last, Oct. 28th :—

	£	s.	d.
Dr. Alfred Cox (monthly)	1	1	0
Sir A. Pearce Gould (monthly)	5	0	0
Dr. Cameron Kidd (for Mrs. Stuart Todd) ...	1	0	0
Dr. F. M. Neild	5	0	0
North of England Branch B.M.A. (per Dr. J. Don, Hon. Sec.)—			
Dr. H. A. Brand... ...	5	5	0
Dr. S. V. Tinsley... ...	1	1	0
Dr. J. W. Smith... ...	5	5	0
Dr. A. Smith, jun. ...	5	5	0
Dr. C. J. Henderson...	1	1	0
Dr. Harris-Liston ...	1	1	0
Dr. Connon	0	10	0
Dr. L. Walker	1	1	0
Dr. G. A. Atkinson ...	5	5	0
Dr. H. H. Aitchison...	5	5	0
Dr. M. A. Wardle ...	1	1	0
Dr. E. F. Pratt	5	5	0
Dr. R. A. Morris... ...	1	1	0
Dr. H. R. Kendal ...	1	1	0
Dr. J. G. D. Cort ...	1	0	0
Archdeacon Henderson	1	1	0
Dr. R. Forsyth	3	3	0
Dr. W. Mussellwhite...	2	0	0
Prof. David Drummond	10	10	0
Dr. H. Kershaw	2	2	0
Dr. W. W. Stainthorpe	2	2	0
Dr. W. Petter	1	1	0
Dr. C. G. Maclagan ...	3	3	0
Dr. J. Hedley	3	3	0
Dr. H. A. Fielden ...	5	0	0
Dr. N. F. Rowstron ...	1	1	0
American Red Cross Commission for Belgium (monthly) ...	200	0	0
Dr. J. C. M. Given ...	1	1	0
Hon. Med. Staff of Bolton Infirmary (per Dr. Mothersole)	25	0	0
Dr. Charlotte E. Warner	1	0	0
Dr. Roy Winn (Australia)	20	0	0
Dr. T. M. Tibbetts... ...	1	1	0
Dr. C. H. Brangwin (China)	5	0	0

Subscriptions to the Fund should be sent to the treasurer of the Fund, Dr. H. A. Des Vœux, at 14, Buckingham Gate, London, S.W. 1, and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

URBAN VITAL STATISTICS.

(Week ended Oct. 26th, 1918.)

English and Welsh Towns.—In the 96 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had increased from 11·4 to 20·7 in the four preceding weeks, further rose to 30·9 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 34·5, or 14·4 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 7·0 in Grimsby, 9·0 in Dewsbury, and 9·9 in Sunderland, to 63·1 in Hull, 67·4 in Bootle, 71·4 in Leicester, 72·1 in Birkenhead, and 74·6 in Oxford. The principal epidemic diseases caused 219 deaths, which corresponded to an annual rate of 0·7 per 1000, and included 81 from diphtheria, 66 from infantile diarrhœa, 25 from measles, 22 from whooping-cough, 19 from scarlet fever, and 6 from enteric fever. The deaths from influenza numbered 4488, against 1895 in the previous week, and included 1256 in London, 233 in Sheffield, 230 in Liverpool, 197 in Leicester, 175 in Portsmouth, 148 in Hull, and 127 in Cardiff. The 1251 cases of scarlet fever and 1200 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 10 above and 5 below the respective numbers remaining at the end of the previous week. The causes of 79 deaths in the 96 towns were uncertified, of which 12 were registered in Liverpool, 11 in Birmingham, and 9 in Portsmouth.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at 2,500,000 persons, the annual rate of mortality, which had increased from 10·6 to 28·3 in the six preceding weeks, further rose to 29·4 per 1000. Of the 1358 deaths from all causes, 57 were classified to influenza, which was also stated as a contributory cause in 457 deaths classified to other diseases; in the previous week these numbers were 63 and 426 respectively. The 732 deaths in Glasgow corresponded to an annual rate of 34·3 per 1000, and included 13 from whooping-cough, 5 from infantile diarrhœa, 2 from enteric fever, and 1 from diphtheria. The 125 deaths in Edinburgh were equal to a rate of 19·6 per 1000, and included a fatal case each of scarlet fever and diphtheria.

Irish Towns.—The 362 deaths in Dublin corresponded to an annual rate of 47·3, or 8·7 per 1000 above that recorded in the previous week, and included 162 from influenza, 3 from infantile diarrhœa, 2 from enteric fever, and 1 each from whooping-cough and diphtheria. The 104 deaths in Belfast were equal to a rate of 13·8 per 1000, and included 4 from infantile diarrhœa and 1 from whooping-cough.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—A clinical meeting will be held to-day, Friday, Nov. 1st, in the society's rooms, West London Hospital. The chair will be taken at 8.30 P.M.

Correspondence.

"Audi alteram partem."

THE STORY OF A "NEW" DISEASE.

To the Editor of THE LANCET.

SIR,—In your interesting editorial article on epidemic catarrh in THE LANCET of Oct. 26th you refer to Dr. F. G. Crookshank's recent Chadwick lectures on "The Story of a New Disease," implying that he really regarded the disease as a new one. I was present at the first lecture and presided at the second, and I can say that his contention—ably supported by arguments and historical references to epidemics of an influenzal type extending as far back as the thirteenth century—was that outbreaks of mental and physical manifestations such as are now grouped under the comparatively new name of "Heine-Medin disease," and of which infantile paralysis is only one of the most striking, had been constantly found attendant upon or had closely followed in obvious connexion with such epidemics. Perhaps Dr. Crookshank would have better entitled his lectures as the story of a "new" disease.

In addition to your valuable prophylactic suggestions with regard to the present epidemic, may I say that if persons entering densely crowded underground lifts and cars were to keep their mouths closed—by preference upon an antiseptic lozenge—and breathe only through the naturally protective nasal passages, and if, further, some simple method of frequently sterilising all public telephones were adopted, the incidence and spread of influenza would be much abated.

I am, Sir, yours faithfully,

London, Oct. 28th, 1918. R. DOUGLAS POWELL.

A NEW TYPE OF INFLUENZA.

To the Editor of THE LANCET.

SIR,—Dr. Wm. Collier's very interesting letter in your issue of Oct. 26th on the clinical aspects of the influenza now raging in so many parts of the world is an important contribution to the literature of the prevailing pandemic. In the main, my clinical experience of the cases observed in the Meath Hospital and County Dublin Infirmary and in my private practice within the past three weeks agrees closely with Dr. Collier's observations. I must state, however, that tachycardia has been more frequently observed in the early stages of an attack associated with extremely high temperatures than bradycardia. The latter condition is of frequent occurrence in the convalescent stage. To-day I counted 42 heart beats per minute in a convalescent patient. Epistaxis has been of frequent occurrence in the severe cases. And I have come to measure the gravity of a given attack by the intensity of the albuminuria which is present. Of this untoward condition Dr. Collier makes no mention. It is apparently of toxæmic origin. Its presence is quickly attended by extraordinary manifestations of delirium and of the ataxic state generally.

It has fallen to my lot to witness a cholera epidemic in 1866, small-pox epidemics in 1872 and 1878–80, and last, not least, the epidemic (or rather pandemic) of influenza in 1889–90, of which Dr. Collier speaks. But, in my opinion, none of those visitations equalled the present outbreak in extent, virulence, or treacherous course. In fatal cases widespread mischief has been found in connexion with the breathing organs. An advancing disseminated or island pneumonia is more frequent than a fibrinous lobar pneumonia. Extensive bronchial catarrh in one direction and pleuritis in the other direction are associated with varying degrees of pneumonitis or of pulmonary sanguineous œdema. But the development of the ataxic state—insomnia, raving, tremor, and dry black tongue, with sordes on the teeth and lips—sufficiently indicates the profoundness of the system-poisoning of this really terrible disease in many instances. The bacteriological findings include Pfeiffer's *Bacillus influenzæ*, the *Diplococcus pneumoniæ* of Fränkel, and a streptococcus, the two latter as secondary infections.

I am, Sir, yours faithfully,

Dublin, Oct. 28th, 1918. JOHN W. MOORE, M.D., F.R.C.P. Irel.

INFLUENZA AND PREVENTIVE INOCULATION

To the Editor of THE LANCET.

SIR,—I venture to criticise the note on administration of vaccine for influenza, published by the War Office, in THE LANCET of Oct. 26th. I find myself wholly at variance with the suggestions of the Committee as regards the dosage of the influenzal moiety of the vaccine proposed, and the following remarks are entirely confined to that portion of the vaccine, as I regard the pneumococcal and streptococcal doses as admirable. The list of gentlemen on the Committee is one of gifted and able bacteriologists of such eminence that to differ from them is a serious matter. But the question of influenza vaccine dosage, in the absence of requisite experimental work thereon, is not a question of pure science so much as a question of practice. This being so, one immediately recognises the scarcity of practitioners on the Committee. It seems to follow, therefore, that the Committee had to depend to a very great extent on the experience of at least a minority of its members in this matter, and to this extent its opinion loses weight. However that may be, I venture to say that the doses proposed, 30 and 60 millions, are inadequate to a degree seriously imperilling the value of the vaccine.

I have been in the habit since July, 1916, of investigating my cases of catarrh with the aid of blood and trypsin-blood plates planted from sputum, nasal swabs, or post-nasal swabs. Particularly have I used the latter in non-catarrhal periods between recurrent attacks of catarrh, and very frequently have I in these conditions demonstrated influenzal infections, and repeatedly have I recovered influenza bacilli from the trypsin plate when the parallel blood plate failed me utterly in this respect. Thus my experience of these infections is extensive. Moreover, all my cases are treated with vaccines prepared on my medium.[1]

As the result, therefore, of more than two years' experience of the medium I am firmly convinced that appropriate and successful therapeutic doses are, except in the case of perhaps the first two or three doses, very frequently larger than the Committee's proposed prophylactic doses. The great difference of opinion between us as to dosage may be accounted for by a possible change of toxicity in vaccine grown on my medium. As the required quantity of vaccine can only be prepared by using my medium, and as this method is in fact being used, the possibility of this change of toxicity becomes important, and it also makes my two years' experience of vaccine prepared by this method more valuable. Another point that bears on this question of dosage is the fact that for some years the mixed cold vaccine issued by St. Mary's and distributed by Parke, Davis, and Co. contains per c.cm. 300 millions of influenza bacilli, grown on my medium. Few, if any, complaints as to general reactions are heard, and yet the doses advised are 0·5 c.cm. and 1 c.cm.

It is, of course, obvious that with the methods of culture available before my method was introduced the quantity of influenza bacilli in a given vaccine was a question of much moment, and it is almost inconceivable that under the old conditions vaccine, even in the attenuated form suggested, could have been provided in a reasonable time for large bodies of troops. This aspect of the matter is entirely changed by my method. Indeed, the issue of the mixed vaccine will certainly not be delayed because of an insufficiency of influenza vaccine. This I can say as I am personally supplying quantities of the vaccine to the military authorities through the Inoculation Department, St. Mary's Hospital.—I am, Sir, yours faithfully,

JOHN MATTHEWS,
Bacteriologist, St. Mary's Hospital.

Wimpole-street, W., Oct. 28th, 1918.

To the Editor of THE LANCET.

SIR,—The extremely interesting account of the proceedings of the Committee appointed by the War Office on the question of the utility of vaccines in the prevention of influenza provisionally suggests that influenza is caused by an unknown microbe, and that the microbes so far discovered in the disease are complicatory and not causal. This is quite a tenable theory and may be true, and the point must still remain *sub judice*. Having watched all the epidemics of

[1] THE LANCET, July 27th, 1918.

influenza since that of 1889–90, I think the following observations are of importance.

For the last 10 years I have examined personally, and not being a skilled bacteriologist, under the supervision of Dr. Matthews, a large proportion of the sputa of patients suffering clinically from influenza. 1. In the majority of cases the bacillus of Pfeiffer has been discovered. 2. In all of the epidemics some other germ has been found present with it. 3. The associated germ has varied in different epidemics. 4. In some *Bacillus influenzæ* has not been found, and the attacks seem to have been due to streptococcus or pneumococcus, and occasionally to other microbes, such as *Bacillus septus*, &c. 5. In long-continued or frequently recurrent cases I have seen rapid cures and prevention of recurrence as the result of a course of vaccine treatment, the vaccine being made from the germ or germs discovered in the sputum.

I therefore venture to suggest that influenza is the name given to a well-recognised fever syndrome, and that it can be the result of any of these germs when they become epidemic. Why a germ is at one time epidemic, at another sporadic, we do not know, but we recognise this feature in other diseases, and also that some epidemics are severe in type, others mild. Influenza never disappears, cases crop up all through the year, and every year sees an epidemic. "Feverish cold" is probably a mild influenza; for the same germs are found in the two diseases.

It therefore seems probable that preventive inoculation will be beneficial, although too much must not be expected, as one attack of influenza does not (like small-pox, for instance) protect for long against a second. It seems to give a temporary immunity and future attacks tend to become milder.

I am, Sir, yours faithfully,

H. A. DES VŒUX, M.D. Brux.

Buckingham-gate, S.W., Oct. 26th, 1918.

To the Editor of THE LANCET.

SIR,—In the summary of the decisions come to at a War Office Conference reported in your issue of Oct. 26th there is one important recommendation which cannot be too strongly emphasised—viz., that the mixed vaccine issued by the R.A.M. College should not be employed as a means of treatment in acute cases. May I suggest, however, that the same objection does not apply to the use of sensitised vaccines? These can be given and in much larger doses without the same risks, and trial might well be made of these in view of the comparative failure of the usual remedies employed in the treatment of the secondary infections which appear to be the chief factor responsible for a fatal issue. Such sensitised vaccines could be prepared at every laboratory centre throughout the country from strains isolated from cases occurring within the range of each centre. While expectoration appears to be absent in many of these cases, there is always a sufficient number available from whom cultures may be obtained, and as fresh cases occur new strains can be accumulated fairly quickly.

The specimens of sputum which I have had the opportunity to examine here, where the epidemic is still of recent origin, appear to contain pneumococci, streptococci, or both, as the predominating organisms. The sputum from one fatal case, for instance, yielded practically a pure growth of a *Streptococcus longus*. In the absence of expectoration, and where time is a factor of vital importance, a mixed sensitised vaccine containing streptococci and pneumococci might be prepared from strains isolated from such cases as are available. This would constitute the nucleus of a stock vaccine to which, when obtained, suitable additions should be made. If such vaccines are to be employed it is scarcely necessary to add that they should be given early, and not when the patient is *in extremis*.—I am, Sir, yours faithfully,

ROBERT DONALDSON, M.D., F.R.C.S. Edin.

Reading, Oct. 28th, 1918.

Dr. R. W. ALLEN informs us in a letter received too late for publication that he has had good results in a series of 50 cases of influenza from the use of intravenous injections of oil of garlic. After determining on himself that 3 mins. of *Oleum allii sativi* could be given with impunity, he administered the oil to patients suffering from influenza in a 10 per cent. solution, using equal parts of alcohol and pure ether as the solvent. The initial dose was 5–10 mins., repeated twice or thrice daily. In patients thus treated cough was relieved, sputum came away more freely, and temperature fell rapidly. In no instance did pneumonia supervene. The only drawback noted was an overpowering smell of garlic in the breath.

NASO-PHARYNGEAL INFECTION AT THE ONSET OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—The chief point at issue in the present controversy is the question of the constancy of the meningococcus in the naso-pharynx of the patient at the onset of cerebro-spinal fever. Staff Surgeon P. Fildes's letter in your issue of Oct. 26th does not help us at all, since he fails to specify to which of the contradictory views previously expressed by him he now inclines. Had his experience of outbreaks of cerebro-spinal fever extended beyond the perihelion of Haslar, perhaps Staff Surgeon Fildes would have realised that carriers of the meningococcus are of two kinds, namely, temporary or chronic, and that during an epidemic the former have been found considerably to outnumber the latter, to whom alone he seeks to confine the term carrier. If he will study particulars of the carefully investigated outbreak at a large military depôt described by Captain J. A. Glover in the *Journal of the Royal Army Medical Corps* of January, 1918, he should have his horizon enlarged upon the subject of carriers. At the height of the outbreak in question the carrier rate among non-contacts in the depôt was found to be over 70 per cent!

In spite of the views of Staff Surgeon Fildes and Major J. Dorgan I still maintain that the constant presence of the meningococcus in the naso-pharynx of the patient at the onset of cerebro-spinal fever indicates that every case may be regarded as an instance of a carrier developing the disease. Once the meningococcus is lodged in the upper respiratory passages, the question as to whether the host becomes a case, a temporary or a chronic carrier, would appear to depend upon the degree of his specific susceptibility or resistance to the particular type of meningococcus operating. Moreover, while the vast majority of carriers escape the disease, even chronic carriers occasionally develop it, as Colonel W. M. Flack has shown.

I am, Sir, yours faithfully,

M. H. GORDON,
Lieutenant-Colonel, R.A.M.C.

Central C.S.F. Laboratory, London, S.W. 1, Oct. 28th, 1918.

*** The opposing views have now been stated and in several directions repeated. It is clear that further bacteriological study of the conditions is required.—ED. L.

TREATMENT OF CONCUSSION APHASIA BY GENERAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—In 1915 I read an article on this subject in THE LANCET (Oct. 30th, p. 977) by Major A. P. Procter, C.A.M.C., who gave three cases of concussion aphasia treated by general anæsthesia with good results. He related a case of a soldier who, while in the trenches, was buried in a dug-out by an explosive shell, and when taken out he became unconscious. After a few days in the hospital he regained his consciousness, but was unable to speak. One day he was allowed to visit the village with some of his companions and while there became intoxicated; in this condition he found his voice and regained his power of speech. The other two cases were treated by ether and during the stage of excitement they were induced to speak.

On account of this useful article I have tried eight patients in Chulalongkorn Red Cross Hospital with successful results.

CASE 1.—Nai M., aged 20, had severe convulsions from tetanus for three days, and when recovered was unable to speak. He was admitted to Chulalongkorn Hospital and was then anæsthetised by ether just enough to induce excitement. At this moment he was asked a few simple questions, such as his name, address, age. At first he tried to utter two or three words with difficulty. Next day he was anæsthetised again; but this time he could speak a few words clearly, and after the third trial he regained power of speech completely. During the intervals of the anæsthesia the patient was roused to speak by asking him a lot of questions.

CASE 2.—Nai A., a cadet, aged 18, during the manœuvres "saw a ghost" and fell down unconscious. He was admitted, anæsthetised twice, and regained speech.

CASE 3.—Nai A., a private, aged 19, was put on scout duty, and was brought in unconscious without any apparent cause. For many days he was drowsy and unable to speak. He was anæsthetised, and could speak on the second trial.

CASE 4.—Nai C., a Chinaman, aged 30, got high fever some months ago and had lost power of speech during the height of the fever. He was anæsthetised and could speak on the first trial.

CASE 5.—Nang Y., a Cantonese, aged 26, came for the treatment once and never came again; perhaps she could speak afterwards and held herself as cured.

CASE 6.—A child, aged 5, got fright while the electric light was out; she saw many dreadful objects during the darkness. She was admitted and anæsthetised and her speech recovered.

CASE 7.—Nang N., aged 27, got high fever and could not speak. When she came to the hospital she had lost her speech for four months; she was then anæsthetised and recovered on the first trial.

CASE 8.—A child, aged 1½, lost speech after a high fever. When the temperature came down to normal for two days she was anæsthetised with chloroform in an operation for unerupted tooth. On the next day she began to cry all day and then regained her speech completely within three days.

These eight cases prove that temporary aphasia due to shock or high fever can be cured by general anæsthesia.

I must thank Captain Phien Sinhajai for his assistance in giving the anæsthetic in these cases.

I am, Sir, yours faithfully,

HLUANG SAKDA BHOLARAKSHA (NAI CHEUNE),
M.R.C.S., L.R.C.P.,
Lieutenant-Colonel; Director, Chulalongkorn
August, 1918. Red Cross Hospital.

INFLUENZA AND NASAL DRILL.

To the Editor of THE LANCET.

SIR,—I should like to draw your attention to the fact that the Hancock system of nasal hygiene described by me for the prevention and treatment of adenoids in your issue of August 24th is also proving a most successful preventive of influenza.

I think it is clear that the "induced sneeze" with its accompanying flow of lymph, followed by "handkerchief drill," is more likely to rid the nose of infection than any nasal douche. The advice so frequently given to "sniff up antiseptic lotions" may, indeed, prove harmful, as the germ-laden dust particles and smuts which nature endeavours to stop at the anterior nares may be carried up to the more vulnerable and sensitive part of the nasal mucosa.

Many of the parents of the children attending the Westminster Health Association clinic, where this system is practised, speak most enthusiastically of the way their children have escaped, although in some cases directly exposed to infection. I am, Sir, yours faithfully,

Hanover-square, Oct. 27th, 1918. ISABEL ORMISTON.

THE BROADENING OF THE PUBLIC HEALTH SERVICE.

To the Editor of THE LANCET.

SIR,—Might I be allowed to express the pleasure which will be caused to many by Lieutenant-Colonel Kenwood's Presidential Address on the Reconstruction of the Society of Medical Officers of Health, and especially by the part in which he advocates the formation of sections of the society representing the several branches of activity of public health officers, administrative school hygiene, tuberculosis, child welfare, and venereal disease? This suggestion was singled out by Sir Arthur Newsholme, who gave it his hearty approval, saying that all these officers were medical officers of health. In view of the probability of the formation of a National Medical Service the doings of the Society of Medical Officers of Health, as representing the oldest and most definite civilian medical service, have an added importance. Those of us who are serving in His Majesty's forces will look forward after the war to a state of affairs in which the many useful features of the naval and military medical services are preserved, and especially the perpetuation of the arrangement whereby a medical man automatically receives the advantage of his increased experience by promotion, no matter the branch of medical work in which he has been engaged. Such an arrangement cannot be said to exist in the Public Health Service as at present constituted.

I am, Sir, yours faithfully,

Oct. 21st, 1918. JUSTITIA.

REGULATION 40 D.—A meeting of protest against Reg. 40 D, D.O.R.A., will be held at the Queen's Hall, Langham-place, on Wednesday next, Nov. 6th, at 7.30. The following resolution will be submitted:—

"This meeting demands the immediate withdrawal of Regulation 40 D under the Defence of the Realm Act."

The chair will be taken by Mrs. Henry Fawcett, and free tickets of entry can be obtained from the Secretary of the Association for Moral and Social Hygiene, 19, Tothill-street, S.W. 1. Seats can also be reserved by small payments.

THE SERVICES.

ROYAL NAVAL MEDICAL SERVICE.

Surgeon Commander (ret.) to be Surgeon Captain (ret.): C. G. Matthews.

Surgeon Lieutenants (temp.): W. A. W. Parkes and H. S. Le Marquand to Haslar Hospital.

ARMY MEDICAL SERVICE.

Major-Gen. Sir Walter G. A. Bedford and Col. B. J. Inniss are placed on retired pay.

Temp. Col. Sir F. Treves, Bt. (Hon. Col., R.A.M.C., T.F.), relinquishes his temporary commission on re-posting.

Temp. Col. H. H. Tooth (Lieut.-Col., R.A.M.C., T.F.) relinquishes his temporary commission on re-posting, and is granted the honorary rank of Colonel.

Capt. (temp. Major) D. W. C. Jones, R.A.M.C., T.F., to be temporary Colonel whilst specially employed.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. F. McLennan to be acting Colonel whilst employed as Assistant Director of Medical Services of a Division.

Major D. G. Marshall (Indian Medical Service, ret.) to be temporary Lieutenant-Colonel whilst specially employed.

Major H. F. Shea to be acting Lieutenant-Colonel whilst specially employed.

Temp. Capt. (acting Major) J. O'D. Egan to be acting Lieutenant-Colonel whilst specially employed.

Capt. D. Pottinger relinquishes acting rank of Major on re-posting.

To be acting Majors: Capts. H. L. Howell, H. C. Todd, F. C. Cowtan, T. J. Hallinan, T. F. P. Breen, Lieut. (temp. Capt.) R. L. Ritchie, Temp. Capts. C. C. Court, W. E. Hallinan, T. T. Higgins, J. M. Renton, R. O. H. Jones, C. R. Wills, H. C. W. Allott, D. F. O'Kelly, Temp. Lieut. A. T. Mackenzie.

Temporary Captains to be acting Majors whilst specially employed: D. K. Henderson, H. D. Robb.

Late temporary Captains granted the honorary rank of Captain: W. Clow, M. B. Arnold.

Temporary Lieutenants to be temporary Captains: W. T. McCutcheon, A. Brown, J. A. O'Regan, G. R. Halloran.

Officers relinquishing their commissions: Temp. Capts. J. Morlet, J. F. C. O'Donohoe, H. L. H. Greer, J. M. Kelly, G. A. Lyons, G. Munro, O. Barton, A. R. O. Milton, L. F. Lovell-Keays (on account of ill-health, and is granted the honorary rank of Captain), H. C. Burbidge (on account of ill-health, and is granted the honorary rank of Captain), W. C. W. Glenny (on account of ill-health), Temp. Lieut. N. Beattie, Lieut. R. B. Fletcher (on account of ill-health contracted on active service, and is granted the honorary rank of Lieutenant), Temp. Hon. Lieut. C. F. Larson.

Canadian Army Medical Corps.

Temp. Capts. (acting Majors) to be temporary Majors; O. S. Waugh, W. G. Lyall, W. L. Mann.

Temp. Capt. F. J. Tees to be acting Major while employed as Surgeon.

SPECIAL RESERVE OF OFFICERS.

Capt. (acting Major) J. G. McCutcheon to be acting Lieutenant-Colonel whilst in command of a Medical Unit.

Capt. S. J. A. H. Walshe to be acting Major.

To be Lieutenants: Second Lieut. F. Holmes (from Unattached List, T.F.), G. P. N. Richardson, W. G. Burns (from Glasgow University Contingent, O.T.C.).

TERRITORIAL FORCE.

Lieut.-Col. (Hon. Col.) H. H. Tooth is restored to the establishment on relinquishing his temporary commission in the Army Medical Service.

Major C. H. Usher is restored to the establishment.

Major (Brevet Lieut.-Col.) F. E. A. Webb, from General List, to be Lieutenant-Colonel on the permanent personnel.

Capt. (acting Lieut.-Col.) (General List) G. E. G. Mackay reverts to acting Major on ceasing to command a Field Ambulance.

Capt. P. J. Sheedy relinquishes his commission on account of ill-health, and is granted the honorary rank of Captain.

Capt. G. Wright is seconded for service with a General Hospital.

Capt. (acting Major) G. B. Gill relinquishes his acting rank on ceasing to be specially employed.

Capts. G. B. Gill, J. L. M. Symns, J. A. Morris, J. L. E. McHugh, D. G. Kennard, and T. B. McKee to be acting Majors whilst specially employed.

Capt. A. Ramsbottom to be acting Lieutenant-Colonel whilst commanding a Field Ambulance.

Capts. (acting Lieut.-Cols.) H. B. Pope and H. A. Macmillan relinquish their acting rank of Lieutenant-Colonel on ceasing to command a Field Ambulance, and revert to the acting rank of Major.

Capts. (acting Majors) D. W. Reese and A. B. P. Smith relinquish their acting rank on ceasing to be specially employed.

Capt. (acting Major) A. G. Hebblethwaite, D.S.O., relinquishes his acting rank on vacating appointment as Deputy Assistant Director of Medical Services.

Capt. R. W. MacKenna to be acting Major whilst specially employed, and remain seconded.

Lieuts. R. S. Moon and A. C. Swanston-Thomas to be Captains.

W. W. Earwaker and A. S. Reeves to be Lieutenants.

ROYAL AIR FORCE.

Medical Branch.—H. T. H. Butt and H. Greenwood (late Captain, R.A.M.C.) are granted temporary commissions as Captains.

D. Cromie, H. Hilliard, and W. Inman are granted temporary commissions as Lieutenants.

Dental Branch.—B. G. Kechnie is granted a temporary commission as Lieutenant.

INDIAN MEDICAL SERVICE.

The services of Major R. F. Steel have been placed at the disposal of the Government of Bombay, and the services of the following temporarily at the disposal of the Government of India: Lieut.-Col. E. F. G. Tucker and Major W. H. Dickinson; Lieut.-Col. J. G. Hojel (for employment on military duty).

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue :—

Killed.

Major J. Morris, M.C., R.A.M.C., was educated at Edinburgh University, and qualified in 1904. He held appointments at the Dinorwic Quarries Hospital and at the Denbighshire Infirmary, and was a member of the R.A.M.C. (T.F.) prior to the war. At the time of going on active service he was in practice at Hyde, Cheshire, where he was also police surgeon and medical referee for several assurance companies. The award of the M.C. was recorded in THE LANCET of Jan. 6th, 1917, p. 38.

Capt. P. J. O'Reilly, M.C., R.A.M.C., attached East Yorks Regiment, qualified in Ireland in 1914, and prior to joining the R.A.M.C. was in practice in Dublin. The award of the M.C. was recorded in THE LANCET of Nov. 18th, 1916, p. 881.

Capt. J. G. MacNeill, Canadian A.M.C.

Died.

Major C. W. C. Myles, M.C., R.A.M.C., qualified in Dublin in 1912, and was in practice at Merthyr Vale, Glamorganshire, prior to joining the R.A.M.C. The award of the M.C. was recorded in THE LANCET of Jan. 12th, 1918, p. 79.

Capt. F. O. Spensley, R.A.M.C., was a student at St. Thomas's Hospital, London, and qualified in 1907. He held an appointment at the Lowestoft Hospital, and prior to joining up was senior assistant medical officer at the Darenth Industrial Colony, Dartford, Kent. He died from pneumonia at the Burdon Military Hospital, Weymouth.

Major R. H. McGillycuddy, M.C., R.A.M.C., was a student at University College Hospital, London, and qualified in 1911. Prior to joining the R.A.M.C. he was in practice in West London. The award of the M.C. was recorded in THE LANCET of Jan. 22nd, 1916, p. 215.

Major (acting Lieut.-Col.) T. C. Rutherfoord, I.M.S., was a student at St. Thomas's Hospital, London, and qualified in 1902. At the time of his death, from malaria, he was in command of a field ambulance.

Surgeon-Commander T. Austen, R.N., was a student at Charing Cross Hospital, London, and qualified in 1888. In 1894, when attached to the *Curacoa*, he had charge of wounded rebels after they had been shelled from their trenches near Apia; and in 1904, when attached to the *Talbot*, he rendered first-aid to the disabled Russian cruiser *Variag* after her engagement with a Japanese squadron at Chemulpo, Corea. He died at the R.N. Hospital, Chatham.

Major H. W. Carson, D.S.O., R.A.M.C., qualified in Ireland in 1905, and joined the R.A.M.C. soon afterwards. The award of the D.S.O. was recorded in THE LANCET of June 8th, 1918, p. 822.

Capt. J. H. Connolly, R.A.M.C., qualified at Edinburgh in 1902 and held appointments at the Throat Hospital, Golden-square, London, at the Chesterfield and North Derbyshire Hospital, and at the Royal Albert Hospital, Devonport. He joined up soon after the outbreak of war, at which time he was in practice at Putney and was surgeon in charge of the throat, nose, and ear department of the Queen's Hospital for Children and chief assistant in the aural department at St. Bartholomew's Hospital, London. He died at the Acheson Military Hospital, Regent's Park, London.

Major J. H. McNicol, M.C., R.A.M.C., was a student at Glasgow University, and qualified in 1909. He was at one time assistant to the professors of pathology and of medicine at Glasgow Royal Infirmary, and prior to joining the R.A.M.C. was in practice at Dennistoun, Glasgow. The award of the M.C. was recorded in THE LANCET of July 10th, 1915, p. 99.

Lieut.-Col. L. P. Demetriadi, R.A.M.C. (T.), was educated at Leeds University, and qualified in 1886. He was in practice at Edgerton, Huddersfield, where he was examiner for the St. John Ambulance Association and medical referee for several assurance companies. He was twice mentioned in despatches, and had command of the West Riding Casualty Clearing Station. He died after a long illness contracted whilst on active service.

Capt. R. D. D. D. Brownson, R.A.M.C., was educated at Cambridge University and at the London Hospital, and qualified in 1908. He held appointments at the Great Ormond-street Hospital, London, and at the London Hospital, and died at Peshawur, India, from influenza.

Lost at Sea.

Dr. T. R. Beale-Browne, West African Medical Service, was a student at Guy's Hospital, London, and qualified in 1901. He was at one time assistant medical officer at the Northampton County Asylum, and later joined the West African Medical Staff. He was lost in the s.s. *Baruta*, sunk in collision early in October.

Previously reported Missing, believed Drowned, now reported Drowned.

Capt. W. J. Enright, Canadian A.M.C., qualified at Laval University in 1897. Prior to joining the Canadian Contingent he was in practice at Port Daniel Centre, Quebec.

Wounded.

Capt. R. McC. Hill, D.S.O., R.A.M.C., attached Argyll and Sutherland Highlanders.
Capt. G. Davidson, R.A.M.C., attached R. Fusiliers.
Major D. McKelvey, M.C., R.A.M.C.
Capt. W. E. Elliot, M.C., R.A.M.C., attd. Dragoon Guards.
Capt. J. M. Elliott, R.A.M.C.
Capt. H. L. Garson, M.C., R.A.M.C.
Major W. W. Wells, R.A.M.C.
Major J. F. Burgess, Canadian A.M.C.
Lieut.-Col. D. P. Kappele, D.S.O., Canadian A.M.C.
Capt. D. G. Gardiner, R.A.M.C., attached Devon Regt.
Capt. E. W. D. Hardy, M.C., R.A.M.C., attd. Lancers.
Capt. J. D. Stewart, Canadian A.M.C.
Capt. H. S. Evans, R.A.M.C.
Capt. H. A. C. Swertz, R.A.M.C., attached Royal Scottish Fusiliers.
Capt. R. Lindsay, R.A.M.C., attached Grenadier Guards.
Capt. J. C. Ogilvie, M.C., R.A.M.C., attd. Border Regiment.
Capt. R. E. Pitts, R.A.M.C., attached Duke of Wellington's Regiment.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported :—

Second Lieut. N. Gardner, West Riding Regiment, attached Lancashire Fusiliers, killed in action, youngest and last surviving son of the late Dr. J. Gardner, of Kelvinside, Glasgow.

Capt. M. J. N. McCreery, Royal Dublin Fusiliers, died of pneumonia, son of the late Lieut.-Col. N. McCreery, R.A.M.C.

Capt. (acting Major) R. C. Lundie, D.S.O., R.E., killed in action, only son of Dr. R. A. Lundie, of Edinburgh.

Lieut. F. T. Maurice, Grenadier Guards, died of pneumonia, elder surviving son of Brevet Col. W. J. Maurice, R.A.M.C., of Reading, Berks.

Capt. H. G. Powers, M.C., killed in action, only son of Dr. C. H. Powers, late of Westend, Hants.

Midshipman J. D. A. Lane, R.N.R., lost at sea, only son of Capt. H. A. Lane, R.A.M.C., of Chelsea, London, S.W.

Major C. W. C. Myles, M.C., R.A.M.C., died of pneumonia, younger son of the late Dr. J. P. Myles, of Birr, Ireland.

AUXILIARY ROYAL ARMY MEDICAL CORPS FUNDS.

The annual general meeting was held at 11, Chandos-street, London, W., on Oct. 25th. Sir Alfred H. Keogh was re-elected President; Lieutenant-General T. H. J. C. Goodwin, D.G.A.M.S., was elected Vice-President; and Major W. F. Brook, Colonel Sir Thomas Crisp English, Colonel J. E. Gemmell, and Lieutenant-Colonel F. S. Irvine were elected to the committee. The report of the recommendation of the Committee for Grants up to Sept. 30th, 1918, was adopted. The list of grants to orphans of officers under the Benevolent Branch totalled just under £400 in 11 separate grants.

At a committee meeting held previously grants were made to orphans of seven officers amounting to £240, and to the widows and orphans of six members of the rank-and-file amounting to £234. These Funds are for the education of the children of officers of the Auxiliary Royal Army Medical Corps who have lost their lives during the present war, or have been severely disabled by it; also for widows and children of similar members of the rank-and-file.

Requests for help, as well as subscriptions, should be addressed to the honorary secretary, 11, Chandos-street, Cavendish-square, London, W. 1.

INDIAN SCIENCE CONGRESS.—The sixth annual meeting of the Indian Science Congress will be held in Bombay from Jan. 13th to 18th, 1919. The Governor of Bombay will be patron of the meeting and Lieutenant-Colonel Sir Leonard Rogers, I.M.S., will be president. The sectional president, medical research, will be Lieutenant-Colonel Glen Liston, I.M.S.

OBITUARY OF THE WAR.

MICHAEL JOSEPH O'FLYNN, M.D.R.U.I.,

LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant M. J. O'Flynn, who died of wounds in France on Sept 24th at the age of 39 years, was son of James O'Flynn, of Six Mile Bridge, co. Clare. He was educated at Black Rock, Dublin, and at the National University of Ireland, taking the degrees of M.B., B.Ch. in 1903, and the M.D. four years later. After gaining experience in resident hospital appointments, making a special study of eye work, he settled down in practice at Neath, Glamorgan, in 1909, and the following year married Florence, second daughter of J. H. Davey, J.P., of Briton Ferry. At the outbreak of war he acted as the local military civil doctor for the district, and in November, 1917, joined the R.A.M.C., when he was attached to various units in France, finally to the 1st Northamptonshire Regiment. He met his death while attending the wounded on the battlefield.

Dr. O'Flynn is described by his friends as one who loved his work and whose genial disposition and untiring devotion to duty made him beloved by a wide circle. He leaves a widow and four children. Two of his sisters are practising medicine.

WILLIAM LESLIE DANDRIDGE, B.A. CAMB., M.R.C.S. ENG.,

LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant W. L. Dandridge, who died of wounds on Oct. 5th, was youngest son of Alfred Dandridge, of Beckenham, Kent. He was educated at Sherborne School, going on in 1912 to Emmanuel College, Cambridge, where he graduated in Arts. In 1916 he went to the Isonzo front with a Red Cross ambulance, returning to England after a few months to complete his medical curriculum. After obtaining the diplomas of the Conjoint Board, he joined the 103rd Field Ambulance in France, and it was while accompanying a party of stretcher-bearers to the front line on Oct. 3rd that he was wounded, surviving his injuries only for a few days. Enthusiastic in his work, and of a bright and cheery disposition, Lieutenant Dandridge will be missed by a large circle of friends. His eldest brother was killed at the Battle of the Somme in August, 1916.

Captain ANDREW ROSS, C.A.M.C., who was killed in action on Sept. 29th at the age of 42 years, was a native of Huron, Ontario, and graduated in medicine at the University of Toronto in 1904. He came overseas in April, 1916, as a private in the C.A.M.C. and went to France in June, 1916, with the 8th Canadian Field Ambulance. In July of last year he obtained a commission and was posted to No. 2 Canadian General Hospital and re-posted to a field ambulance in September, 1918.

FREDK. HOYSTED BRADLEY, M.B., CH.B. EDIN.,

DISTINGUISHED SERVICE ORDER;
LIEUTENANT-COLONEL, ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel F. H. Bradley, who was killed in action on Sept. 22nd, at the age of 34, was youngest son of the late Canon Bradley, of Monaghan, Ireland. He was educated at Campbell College, Belfast, where he held a scholarship, and at Edinburgh University, where he graduated M.B., Ch.B. in 1906. After graduating he filled the posts of house physician and resident medical officer at the Stanley Hospital, Liverpool, and entered the R.A.M.C. in 1908, seeing service in various stations at home before he was sent to India in 1910. He went to France in the second month of the war and served there continuously until his death. Latterly he was in command of the 15th Field Ambulance, and was awarded the D.S.O. in January of the present year. A friend and colleague writes of Colonel Bradley: "I had known him ever since he came as O.C. to the ambulance, and he has always shown the greatest kindness and consideration for all his officers. When there was any difficulty he was always ready to come to one's help, and in times of danger he was always ready to take his part."

Colonel Bradley married in 1912 Esther Ellen Lacey, daughter of the late William Hargreaves, of Liverpool, who predeceased him.

WILLIAM BOYD JACK, M.D. GLASG.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain W. B. Jack, who died of wounds on Oct. 11th, was a student at Glasgow University, graduating M.B., Ch.B. in 1905 and taking his doctorate three years later. He held successive house appointments at Glasgow Royal Infirmary before joining Dr. W. B. Cockill in private practice at Kendal in 1907. He was an able and conscientious practitioner, who quickly gained the esteem of all and the gratitude of many. His fellow-practitioners felt that they had in him a steadfast and loyal comrade, and his never-failing kindness and courtesy endeared him to a wide circle of patients and friends. In 1911 he joined the staff of the Westmorland County Hospital, where his sound judgment and professional knowledge were of the greatest value to the patients and help to his fellows. He obtained a commission in the R.A.M.C. in March of last year and was attached to a Leicestershire regiment. In May last he was gassed, and it was while advancing with his regiment in the fight for St. Quentin that he received the wounds which he himself quickly recognised as mortal. The deepest sympathy goes to his wife and three young children.

Captain HERBERT ANTHONY CULHAM, C.A.M.C., who was killed on Oct. 4th, aged 35 years, was a native of Hamilton, Ontario, and graduated in medicine at the University of Toronto in 1910. He came overseas in October, 1916, serving with units in England until November last, when he went to France with No. 2 Canadian Field Ambulance. At the time of his death he was attached to a brigade of Canadian Field Artillery.

Obituary.

ROBERT BRUDENELL CARTER, F.R.C.S.,

CONSULTING OPHTHALMIC SURGEON TO ST. GEORGE'S HOSPITAL; FORMERLY PRESIDENT OF THE MEDICAL SOCIETY OF LONDON.

ONLY a few weeks ago we announced Mr. Brudenell Carter's ninetieth birthday, and on Wednesday evening in last week his long life came to an end. It is 50 years since he first joined the staff of THE LANCET, and in those early years of his connexion with us his forcible editorial contributions made a weekly appearance in our columns. Then for some years, especially during the last 20 years of the past century, his public work made it inconvenient for him to assist us, but in 1899, having by that time ceased to be a member of the General Medical Council, he resumed his close editorial connexion with us. As age grew on him his contributions became less frequent, but, nevertheless, his clear and vigorous leading articles were always acceptable to our readers; on his eightieth birthday he wrote a leading article on the same subject for the *Times* and THE LANCET in which identical general views were expressed, but in which he exactly hit off in the arguments employed and the methods of employing them the due variations in the audiences he was addressing. As late as 1915 in a private letter to the present editor of THE LANCET, who had mentioned that the war had depleted his staff, Carter observed: "You speak of being short-handed; if this refers to writers I might possibly do something to help, and I need not say that you could command my services although I should not like to attempt writing under much pressure as to time." He was then 87 years of age. Carter's death is truly for us a break with the past.

Robert Brudenell Carter, the son of an officer in the Royal Marines, was born at Little Wittenham, Abingdon, in 1828, and entered the medical school of the London Hospital at the age of 19, after having served the course of apprenticeship to a general practioner which in those days was the orthodox method of entering the medical profession. He became M.R.C.S. in 1851 and L.S.A. in the following year, when he went into general practice in the north of London. But in the spring of 1854, when England and France declared war against Russia, Carter, like many other young surgeons, went to serve in the Turkish Army in a voluntary capacity, and while there he contributed both to the *Times* and THE LANCET letters and papers of his Crimean experience. The letters to the *Times* had a great future influence on his career. On his return to England he again went into general practice in suburban London, and then left for Nottingham, where he remained for some years, and where he was first attracted to ophthalmology in particular, while writing also on general medical subjects Later he moved to Chatham, and in 1868, being then 40 years of age, he came up to London, deciding to tempt fortune as an ophthalmic surgeon, being now in possession of the F.R C.S. This bold step he has described in a further letter to the editor of THE LANCET in the following words:—

"My life generally is calculated to encourage hopefulness under adverse circumstances. Up to the age of 40 I was a conspicuously unsuccessful general practitioner in the country. In my forty-first year I decided to burn my very small and shallow boats and to come to London. Within a year I was a leader writer for the *Times*, a constant contributor to the editorial columns of THE LANCET, and surgeon to the Royal South London Ophthalmic Hospital. Within two years I was ophthalmic surgeon to St. George's and my way was fairly clear.

I think it is a point in my favour that, as I could not afford the six years' hospital practice as a student necessary for the Fellowship of the Royal College of Surgeons, I determined from the first to maintain my knowledge of anatomy and to keep fully abreast of surgery. The result was that as soon as I had completed the necessary 12 years as a Member, I was able to go up from my country practice for the Fellowship examination without either rest for study or coaching, and to pass. But for this, of course, I could not have obtained hospital posts.

Pray excuse my troubling you with this yarn about myself, and please excuse the bad writing. I am in a reclining chair and write on a pad held in my left hand."

From 1870 until 1893 Carter was ophthalmic surgeon to St. George's Hospital, and during all that time he conducted a large ophthalmic practice and communicated to the professional world some admirable work on eyesight generally. His lectures on Cataract, on Eyesight in Schools, on Optical Appliances, and on the General Cause of Good and Bad Eyesight were all valuable expositions on questions that required to be treated in a plain manner by a well-informed writer.

In 1881–82 he was Hunterian professor of surgery and pathology in the Royal College of Surgeons of England, and shortly afterwards was elected President of the Medical Society of London, having in 1884 been Lettsomian lecturer. A Knight of Justice and Honorary Commander of the Order of St. John of Jerusalem, he was consulting surgeon to the ophthalmic hospital at Jerusalem; while his knowledge of French, which equalled his knowledge of German, was placed at the disposal of the cause of sanitation generally when he became Foreign Secretary to the French Society of Hygiene. In 1893 he was, after 23 years' service, elected consulting ophthalmic surgeon to St. George's Hospital and also to the Royal South London Ophthalmic Hospital.

In 1875 appeared his "Practical Treatise on Diseases of the Eye," which was at once recognised as a valuable addition to ophthalmic literature. An extremely skilful man of letters, he got over the difficulty supremely well which a specialist has in writing a text-book. Such a medical author may propose to write for the benefit of the general profession, discovering for them the principal points of his own branch of practice, or he may write as a specialist for specialists, submitting his own views and practice to expert criticism. Carter managed to do both things. He gave a general view of the present state of knowledge with regard to the nature and treatment of the more important diseases of the eye, but from individual experience he was able to add original suggestions and to subject the work and views of other well-known specialists to just and lively criticism. His whole object was to see general practitioners skilful in detecting and treating eye disease, and he placed in their hands a manual of great value to that end. Several editions of his book were issued, edited by himself and later by Mr. W. Adams Frost, while he also wrote the articles on Diseases of the Eye in "Quain's Dictionary of Medicine," and the section of ophthalmic surgery in "Holmes's System of Surgery." He also translated Zander's original work on the ophthalmoscope and Scheffler's "Optical Defects of the Eye." Carter's contributions to medical and special scientific literature were, it will be seen, numerous, and they always possessed the particular virtues of clearness and force. Eloquent, incisive, more than occasionally bitter, he was also a generous writer, and few members of the medical profession have wielded greater power with the pen, while he possessed the equally valuable gift of being able to speak in public with the same command of language and high level of literary style. Carter's "leaders" belong to an older day—he used the Latin "period" and orotund full-dress methods—but any appearance of pomposity thus given to his writings was purely superficial; no writer of to-day is more fastidious than was Carter in his choice of language or more resolutely averse from the use of stale metaphors, trite tags, and obvious morals.

Clear speaking and close debating made him during his 20 years on the General Medical Council a force in the proceedings of that body, and strongly conservative member although he always was, it should be placed on record that he was the author of that change in the methods of the Council by which it was rendered possible to deal in a suitable measure with comparatively trivial professional offences. Carter devised the expedient of postponing decision upon small offences until the next session, the interval being thus rendered a period of probation. When he joined the Council there were many cases in which there was no choice but to inflict the penalty of erasure from the Register for quite trivial offences or else to condone them altogether. Even if they came within definitions of "infamous conduct," which the Council had already laid down, cases of "covering an unregistered practitioner," for example, differed immensely as to degree of turpidity. More than once men who had but just entered the profession were expelled from it for what was little more than foolish good nature and which only needed an admonition, and this was the cruelty that Carter set out to right. Since he succeeded in introducing the change there has been scarcely a session in which it has not been brought into useful operation.

Carter was of ancient family, being eleventh in descent from Thomas Carter, a gentleman bearing arms who was settled at Higham, Bedfordshire, in the reign of Edward IV. He married first Helen Ann Beauchamp, daughter of John Becher: and secondly Rachael Elizabeth, daughter of Stephen Hallpike and widow of the late Walter Brown. By his first wife he had four sons.

This is but a brief chronicle of a long and busy career, but Carter's life in far greater detail is chronicled in "Doctors and their Work," a volume which he wrote some 15 years ago.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Housing Bill.

A SECOND reading was given to the Housing Bill in the House of Commons on Monday, Oct. 28th, but a certain amount of criticism arose on the fact that its scope was limited. Mr. HAYES FISHER, the President of the Local Government Board, however, explained in moving the second reading that the Bill was only an instalment of the Government programme which he had unfolded to the House in May during the discussion on the estimates of his department. That programme would again be brought before the House in a much larger measure dealing with the whole of the financial aspects of the problem and incorporating many other means by which the action of the State could be linked up with that of local authorities, public utility societies, and also, he hoped, private enterprise. The right honourable gentleman could not say when that measure would be introduced. The first clause in the present Bill gave financial encouragement to county councils to build houses for their own employees. The second clause gave powers whereby where the smaller local authorities had not taken adequate steps to provide houses for the population of their areas the Local Government Board should have the right to call in the county council to carry out the duty. Several honourable Members emphasised the connexion of housing and health, and expressed regret that the Government had not brought forward a larger measure now.

The Midwives Bill.

The Midwives Bill was read a second time in the House of Lords on Tuesday, Oct. 29th. As the Bill now stands, Clause 12 repeals Section 9 of the Midwives Act, 1902, which enabled county councils to delegate their powers over midwives to district councils. Where such delegation has already occurred, it shall not be affected unless the county council concerned, with the consent of the Local Government Board, withdraws the delegation.

HOUSE OF COMMONS.

WEDNESDAY, OCT. 23RD.

Cooking in Military Hospitals.

Answering Mr. GILBERT, who asked whether there were many complaints as to the way in which food was cooked in London Military Hospitals, Mr. MACPHERSON (Under Secretary for War) wrote: Some complaints of the nature mentioned have been received, and an officer from the War Office has been sent to investigate the matter and make suggestions with a view to improvement. I would add that the whole question of cooking in military hospitals is receiving close attention, and the appointment of expert lady cooks to act as inspectors of cooking in military hospitals is at present under consideration.

Prevention of Anthrax.

Mr. JOWETT asked the Home Secretary what action he had taken to secure the disinfection of dangerous wool since he received the report of the Departmental Committee which reported, on Nov. 23rd, 1917, that at a very small net cost infected wool could be rendered free from danger from anthrax.—Sir G. CAVE replied: The honourable Member refers presumably to the preliminary report of the Disinfection Subcommittee of the Departmental Committee which was received and presented to Parliament last spring. The report deals only with the results of the investigation into methods of disinfection; it contained no proposals for applying its conclusions, and in the covering letter submitting the report the Committee expressly advised that no action should be taken pending their final recommendations. The final report, which is being issued to-day, was only received last month. It makes a series of far-reaching proposals, involving the erection of disinfection stations abroad as well as in this country, the establishment of a special authority, and international coöperation. These proposals will be considered and the necessary action taken without delay.

THURSDAY, OCT. 24TH.

Venereal Disease and Regulation 40 D.

Mr. LEES-SMITH asked the Home Secretary whether any provision was to be made by which women who were arrested under the Defence of the Realm Act, Regulation 40 D, and against whom no conviction was obtained, were to receive compensation for undergoing the special medical examination for venereal disease.—Sir G. CAVE answered: The reply is in the negative.

Mr. LEES-SMITH: Has the right honourable gentleman taken into account the statement made last week that of the prosecutions made under this regulation, almost one-half of the women are found to be not guilty, but although not guilty they are subjected to this examination, which is a terrible penalty in itself; and will he either give them compensation or withdraw the regulation?—Sir G. CAVE: No, Sir, when the examination is made it is made by consent.

Mr. LEES-SMITH: Is the right honourable gentleman aware, with regard to his statement that this examination is made by consent, that the prosecutor for the Government stated that if the women refused to undergo the examination it would be taken as proof against them?—Sir G. CAVE: I am not aware of that. It would not be a proper statement to make.

Mr. LEES-SMITH asked whether the right honourable gentleman would now issue instructions that the consent of women to undergo the special medical examination for venereal disease provided for in the Defence of the Realm Act, Regulation 40 D, should in all cases be obtained in writing.—Sir G. CAVE replied: The question is under the consideration of the committee recently appointed.

Medical Men and the Pensions Ministry in Ireland.

Mr. NUGENT asked the Parliamentary Secretary to the Ministry of Pensions whether he had refused applications for employment under Government by medical officers who had previously served in any capacity under the National Insurance Commissioners in Ireland, irrespective of previous long or active service; and, if so, whether he would explain why this course had been adopted, in view of the promise given by the Prime Minister.—Sir A. GRIFFITH-BOSCAWEN said in reply: I am not aware of any ground for this suggestion. The selection of medical men to act as referees in Ireland was entrusted by the Minister of Pensions to a committee specially appointed for the purpose, consisting of representatives of the Irish Local Government Board, Irish Insurance Commission, Ministry of Pensions, Ministry of National Service, Irish Medical War Committee, President of the Royal College of Surgeons, and Irish Medical Committee. The report received from the committee shows that very great care was exercised in the duty entrusted to them and that the medical men selected were unanimously agreed to.

Medical Women in Military Hospitals.

Sir P. MAGNUS asked the Under Secretary for War whether, having regard to the fact that medical women serving in military hospitals discharged similar duties and received the same pay as men doctors and were entitled to wear the Royal Army Medical Corps badge, he would take steps to rectify the anomaly of their being refused even honorary commissions or to wear badges of rank which would be helpful to them in maintaining discipline; and whether he could arrange that they should obtain equivalent relief from income-tax as was granted to men doctors under the service rate.—Mr. MACPHERSON replied: I am reconsidering this question. Perhaps my honourable friend will be good enough to ask me a question on the subject next week. The last part of the question is one for the Treasury.

Effect of Occupations on Women's Health.

Mr. ROWNTREE asked the Minister of Reconstruction whether, in preparation for the task of demobilisation, any careful inquiry had yet been made into the effect of different occupations on the health and physique of women; and, if so, could the result of such inquiry be made public.—Dr. ADDISON wrote in reply: In addition to the reports of the Health of Munition Workers Committee, which has recently been published, the Home Office has undertaken an inquiry into the question referred to. The inquiry is now completed and the question of publication is a matter for the Home Secretary.

Rabies and the Pasteur Treatment.

Mr. R. MCNEILL asked the President of the Local Government Board whether, in view of the danger arising from the existence of rabies in the country, he would issue information to the public as to what facilities there were for obtaining Pasteur treatment, and as to the steps that should be taken by individuals who might be bitten by suspected dogs.—Mr. HAYES FISHER replied: A circular on the procedure to be adopted was sent to medical officers of health in Devonshire and Cornwall as soon as the Local Government Board was informed of the presence of rabies among dogs in these counties. It has now been revised, and a copy of the revised circular will be sent to the press.

Maternity Benefit.

Sir C. KINLOCH COOKE asked the President of the Local Government Board whether he was aware that cases had arisen where women, insured under the National Insurance Act, had taken advantage of the workhouse for their confinement and subsequently drawn the maternity benefit; and would he consider the advisability of making some provision so that in cases of this kind guardians might be in a position to apply for and receive some portion of this benefit.—Mr. HAYES FISHER answered: The reply to the first part of the question is in the affirmative. In view of the provisions of Section 111

of the National Insurance Act, 1911, and Section 20 of the National Insurance Act, 1918, I could not take the action suggested in the latter part of the question.

Sanatorium Treatment.

Replying to Mr. BOWERMAN, Sir E. CORNWALL (representing the National Insurance Commissioners) wrote: Some 30,000 insured persons annually have, since the National Insurance Act, 1911, came into operation, received residential treatment for tuberculosis in sanatoria and hospitals in addition to the large numbers which have received dispensary and domiciliary treatment. But this still leaves a regrettable number of cases for which accommodation is lacking. The war has made serious difficulties in regard to building operations and other matters involved in providing more institutional accommodation.

MONDAY, OCT. 28TH.

The Influenza Epidemic.

Mr. DENMAN asked the President of the Local Government Board whether he could make any statement as to the prevalence of an epidemic of influenza; whether it was causing a rise in the rate of mortality; whether it was associated with other diseases; and what steps were being taken by his department and should be taken by the public to combat it.—Mr. HAYES FISHER replied: The present epidemic of influenza is causing a considerable rise in the rate of mortality, as will be seen from the weekly returns of the Registrar-General, but happily the rise is not so great as that experienced in Vienna and Paris, and, I believe, in other such large towns. Numerous conferences have taken place between representatives of my department, of the naval and military authorities, and the Board of Trade in regard to the transport of troops. The medical officers of my department have also been in consultation with the Army Medical Department and the Medical Research Committee, and bacteriological investigations have been continuously made since the commencement of the summer outbreak. These show that bacteriologically this outbreak does not differ from other outbreaks of influenza, the fatality being due to secondary infections chiefly by pneumococci and streptococci. I have also called a special conference of the representatives of all the departments concerned. As to the steps which can be taken by the public, I may refer to the memorandum of my medical officer which has been issued. This memorandum emphasises the fact that control over this catarrhal disease is only practicable by the active coöperation of each member of the community, and medical officers of health have brought the precautions recommended by the memorandum to the notice of the local public by means of special leaflets and in other ways.

Mr. DENMAN: Are we to anticipate a Ministry of Health in the near future?—Mr. HAYES FISHER: I do not think that arises.

Colonel C. LOWTHER: Is it a fact that there are two distinct epidemics—influenza and septic pneumonia?—Mr. HAYES FISHER: I do not think that we can say that there are two.

Mr. PONSONBY: Is the spread of this disease largely due to malnutrition?—Mr. HAYES FISHER: I have no reason to think that that is the case.

Mr. PRINGLE: Will the right honourable gentleman make representations to the National Service Department to refrain from calling up further medical men, and to the War Office to release more medical men from the Army for civilian service?—Mr. HAYES FISHER: I am sure the Minister of National Service must have taken notice of the fact that medical men are seriously wanted in every department of civil life.

Administration of Medical Benefit.

Mr. CURRIE asked the representative of the National Insurance Commissioners whether his attention had been drawn to the difficulty arising out of the issue of his Departmental Circular 242 X, dated June, 1918, which would result in numbers of insured persons losing medical benefit by reason of their earnings now exceeding £160 a year; whether he would, by legislation or otherwise, take steps to prevent this result, in view of the fact that £160 was now of less value than £100 when the 1911 Act was passed; and whether meantime he would suspend or modify the said circular.—Sir E. CORNWALL answered: In view of the numerous inquiries received as to the position in insurance of non-manual workers in receipt of war bonuses or other increase in wages bringing their rate of remuneration to over £160 a year the Commissioners felt that the question could no longer be left in uncertainty, and a circular to which my honourable friend refers sets out what the Commissioners are advised to be the legal position in such cases. The difficulty, of which I am fully aware, arises not from the circular but from the general increase in wages. There is no intention at present to introduce amending legislation on the subject.

TUESDAY, OCT. 29TH.

Medical Services and the Influenza Epidemic.

Mr. TYSON WILSON asked the Minister of National Service what steps he had taken to provide an adequate medical service for the civil population in view of the present serious epidemic of influenza.—Sir AUCKLAND GEDDES replied: All arrangements made in connexion with the employment of medical men under the Ministry of National Service and all withdrawals of medical men from civil life for service with the armed forces of the Crown during the past year have been made with full regard to the contingency of a widespread epidemic disease affecting the population. Influenza has been more or less prevalent in epidemic form for some months, and the calls on the civil medical profession have been consequently very heavy. Simultaneously, severe fighting on a great scale in all theatres of war has imposed an additional heavy strain on our medical resources. In April Parliament conferred powers on the Minister of National Service which enabled him to examine men of military age at any time. In view of possible emergencies this power was largely used, approximately 7000 medical men being employed and very large numbers of men being examined. Concurrently with the increase of influenza the number of medical men employed on Medical Board work has been reduced, thereby rendering an increasingly large body of medical men available for exclusively civil practice. The number of Medical Board sessions has been reduced from approximately 3500 to 1000 per week. This has not affected recruiting, as the pool formed by examining men in advance has been sufficient to maintain the flow of men to the forces. In order further to reinforce the doctors available to attend the civil population I have given instructions that all medical examinations in advance are to be suspended for the present. Pensions examinations and the examinations of men reporting for service will, of course, continue. Arrangements have also been made to reinforce the medical staffs available at hospitals so far as our resources will permit. In conclusion, I should like to express my deep appreciation of the way in which the medical profession has coöperated with the Ministry of National Service in meeting unprecedented and often conflicting demands for medical personnel.

Mr. PRINGLE: Has the right honourable gentleman any information as to the effect of the influenza epidemic on medical men themselves, and is he prepared to suspend for the present any further calling up of them?—Sir AUCKLAND GEDDES: I have not got any complete figures showing the numbers of medical men who are down with influenza, but I know the numbers have been considerable. We have released from calling upon their time a very large number of medical men who are now devoting the whole of their time to civil practice. We are putting at the disposal of districts where we can full-time medical men. We cannot create medical men for the emergency, but we have to do the best we can to spread the resources we have. It happens that at the moment there is a very heavy demand for young fit doctors for the front. The casualties amongst the medical profession have been very heavy, and we have had to call up a certain number of young fit men because we have nobody else to send to the front. By the front I mean the real fighting line. We have arranged that a certain number of young naval surgeons shall go to France, and they have gone. We are doing our best to have the older and less fit men made available here. The pressure is so great that it is not a simple problem for us to move the men to the place where they are most required.

Mr. PRINGLE: Will the right honourable gentleman secure that no medical practitioner over 40 may be sent out of the country now?—Sir AUCKLAND GEDDES: It would be very difficult to give a pledge, but we are doing the best we can with the resources at our command.

R.A.M.C. Officers in India.

Colonel YATE asked the Under Secretary for War what arrangements had now been made for the relief of time-expired Royal Army Medical Corps officers who had been retained in India since the commencement of the war and had had no opportunity for service at the front.—Mr. MACPHERSON answered: Twenty-four officers have been sent to India in relief of a similar number of time-expired, and two are awaiting passage. Until the relieved officers return home it is impossible to spare further officers for the purpose, as the system involves the loss of the services of the officers for a period of two to three months.

R.A.M.C. Officers, Territorial Force.

Sir FRANCIS BLAKE asked the Under Secretary for War whether a general promotion list for officers of the Royal Army Medical Corps, Territorial Force, had now been prepared and published; and whether he would state the authorised establishment of colonels, lieutenant-colonels, and majors in that force, and the existing number in each rank.—Mr. MACPHERSON replied: In accordance with

the recommendations of the Committee on Promotion of Officers in the Special Reserve, New Armies, and Territorial Force, a seniority list has been prepared for all officers of the Royal Army Medical Corps, Territorial Force, other than the administrative and *à la suite* staffs of Territorial Force General Hospitals and the Sanitary Service. This list is included in the Army List. The establishment authorised is: colonels 19, lieutenant-colonels 107; and the existing officers of these ranks are colonels 9 and lieutenant-colonels 75. Promotion to the rank of major being governed by a time-qualifying period, the establishment of this rank is not limited. The actual promotions consequent upon the determination of the establishments to which I have referred are under consideration and will be published as soon as possible after the receipt of the information which it is essential to obtain from various theatres of war where the officers concerned are serving.

WEDNESDAY, OCT. 30TH.

The Influenza Epidemic.

Mr. ROWNTREE asked the President of the Local Government Board whether in view of the continued spread of influenza he would state to the House how many medical advisers there were attached to the Local Government Board, whether they were all at present engaged in giving their whole time to preventive measures dealing with the epidemic, whether in view of the grave results arising from the spread of the disease he considered the staff wanted strengthening, and whether he did not think it advisable to issue broadcast advice as to what steps could be taken by the public to prevent the spread of infection.—Mr. HAYES FISHER replied: The staff of the Medical Department of the Local Government Board consists of a medical officer and four assistant medical officers, together with 20 medical inspectors. A memorandum of instruction as to the preventive measures available, which was prepared by the medical officer, has been issued to every sanitary district in England and Wales, and the sanitary authorities, under the advice of their medical officers of health, are urging the adoption of the preventive measures in their several districts. In the invaded towns information as to the precautions available has been distributed broadcast by means of leaflets, posters, and press notices. In many of these areas day schools and Sunday schools have been closed and the public have been advised to avoid crowded assemblies. In some instances voluntary arrangements have been made for excluding children from cinema performances, and also for increasing the time between performances so as to allow the air in the building to be thoroughly changed. The medical staff of the Board are devoting all such time as is necessary to this epidemic and will continue to do so. I do not at present consider that the staff needs enlargement in consequence of the epidemic.

Answering supplementary questions, Mr. HAYES FISHER expressed the view that the information which it was advisable to bring to the notice of the public was best communicated through the channel of the medical officers of health. He was quite ready to make further inquiries how far this had been effectively done. Conferences had been taking place during the last few days to which the medical officer of the Board of Education had been contributing his wide experience and knowledge. He would give his attention to cases of sanitary districts where there was at present no medical officer of health acting.

Mr. ROWNTREE asked the President of the Board of Education whether in view of the continued spread of influenza he would state what was the view of the Medical Department of the Board regarding the advisability of closing schools at the first appearance of influenza in the school; and whether he thought it desirable to issue some general advice as to what steps could be taken to prevent the spread of infection through the association of so many children.—Mr. HAYES FISHER answered: The closure of schools or the exclusion from school of children suffering from infectious diseases, including influenza, is a matter which rests with the local education authorities or the governors of the schools concerned. Appropriate directions issued by the Board of Education in conjunction with the Local Government Board for the prevention of the spread of infectious diseases occurring among children attending public elementary schools have long been in the hands of all local education authorities and school medical officers. The wisdom or propriety of closure or other action is obviously dependent on the local conditions of the case, upon which it is, of course, impossible for the Board to pronounce. Among such conditions is the degree of prevalence and severity of the disease, as well as the home or other alternative circumstances of the children thus excluded from school. The case of each school must be determined on its merits. It is, of course, essential that all children suffering from catarrhal symptoms, feverishness, or other illness, should at the present juncture be at once excluded, and in many cases it will be found advisable to close the whole school or, at least, departments or classes in the school. As a rule, school closure is more effective in rural districts than in towns. Playgrounds should not remain open when schools are closed. As regards the second part of my honourable friend's question, I have not, up to the present, thought it necessary to issue any general advice of the nature suggested by him. It is obviously impracticable to consider school children separately from other sections of the population which are not within the province of the Board of Education.

Answering Mr. A. WARD respecting a serious epidemic of influenza at the R.A.F. camp at Blandford, Dorset, Major BAIRD (Under Secretary to the Air Ministry) stated that the prevailing influenza epidemic reached the camp on Sept. 21st and had continued to the present date. The number of cases increased in the week ending Oct. 26th, during which 252 cases were reported. Of these 198 were sent to hospital. The number of deaths since Sept. 21st was 59. The average daily strength of the camp was about 15,000. Since the epidemic started five additional doctors and 19 additional nurses had been sent to deal with the situation. For administrative reasons, independent of the epidemic, the drafting of recruits to the camp had been stopped for a period of one week.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.1.

MEETINGS OF SECTIONS.

Wednesday, Nov. 6th.

OPHTHALMOLOGY (Hon. Secretaries—Leslie Paton, Malcolm Hepburn): at 8.30 P.M.

Presidential Address:

Mr. W. T. Holmes Spicer: Changes in the Cornea after Inflammation.

Papers:

Dr. J. B. Christopherson and Major Archibald: Nocardia (Lutea) of the Lacrymal Gland.

Major Fenwick: Brittle Bones and Blue Sclerotics.

Thursday, Nov. 7th.

OBSTETRICS AND GYNÆCOLOGY (Hon. Secretaries—Comyns Berkeley, J. S. Fairbairn): at 8 P.M.

Presidential Address:

Mr. J. D. Malcolm: Developments in Abdominal Surgery since 1834.

Paper:

Mr. John Adams: The Treatment of Ante-natal and Post natal Syphilis.

Members of other Sections are specially invited to attend.

Friday, Nov. 8th.

EPIDEMIOLOGY AND STATE MEDICINE (Hon. Secretaries—William Butler, M. Greenwood): at 5.30 P.M.

Paper:

Capt. Hawn, Capt. Hopkins, and Capt. Meader (U.S.A. Expeditionary Force): Outbreak of Typhoid Fever in Inoculated Soldiers.

RÖNTGEN SOCIETY, at the Royal Society of Arts, 18, John-street, Strand, W.C.

TUESDAY, Nov. 5th.—8.15 P.M., Dr. G. B. Batten: The Presidential Address (illustrated by lantern slides).

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, Nov. 4th.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. D. Armour: Operations. Mr. B. Harman: Diseases of the Eye. Dr. Simson: Diseases of Women.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Baldwin: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Arthur Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. D. Armour: Operations. Mr. B. Harman: Diseases of the Eye.

FRIDAY.—10 A.M., Dr. Simson: Gynæcological Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Baldwin: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

SATURDAY.—10 A.M., Dr. Arthur Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Out-patients each day at 2.30 P.M.

THE THROAT HOSPITAL, Golden-square, W.

MONDAY, Nov. 4th.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.

Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—

WEDNESDAY, Nov. 6th.—4 P.M., Lecture V.:—Prof. J. M. Beattie, M.D.: Infection and Disinfection in War Time, especially in Regard to the Present Outbreak of Influenza.

Appointments.

COOPER, J. S., L.R.C.P. & S. Edin., L.F.P.S. Glasg., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Clitheroe District of the counties of Lancs. and Yorks.

DESAI, H. M., D.Ch.O. Liverp., Surgical Officer in Charge, Durham County and Sunderland Eye Infirmary.

Vacancies.

For further information refer to the advertisement columns.

Birkenhead Borough Hospital.—Jun. H.S. £170.
Birkenhead Union.—Sen. and Jun. Res. Asst. M.O's. £350 and £300.
Birmingham City Sanatorium and Anti-Tuberculosis Centre.—Jun. Asst. M.O. £350.
Birmingham, Erdington Infirmary.—First Asst. M.O. £375.
Bristol Royal Infirmary.—H.P. and H.S. £120.
Cambridge, Addenbrooke's Hospital.—H.S. £300.
Chichester, Graylingwell War Hospital.—Res. M.O. £1 per diem.
Dagenham (Temporary) Sanatorium.—Res. M.O. £300.
Dorchester, Dorset County Council Education Committee.—School Dentist. £350.
Edinburgh, Scottish Women's Hospitals.—Female Asst. M.O. £300.
French Red Cross, 9, Knightsbridge.—Dental Surgeons.
Glamorgan County Asylum, Bridgend.—Temp. Asst. M.O. £6 6s. p.wk.
Holborn Borough Council.—M.O. 52 guineas.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. £100.
Huddersfield County Borough.—Female Asst. M.O.H. £400.
Leeds City Infectious Diseases Hospital, Seacroft.—Asst. M.O. £300.
Leeds City Public Health Department.—Female Med. Asst. £400.
London Temperance Hospital, Hampstead-road, N.W.—Medical Registrar. 40 guineas.
Manchester County Asylum, Prestwich.—Locum Tenens. £7 7s. p.wk.
Manchester Education Committee.—Two Temp. Asst. M.O's. £400.
Manchester Northern Hospital for Women and Children, Park-place Cheetham Hill-road.—H.S. £150.
Montgomeryshire Education Committee.—School Dentist. £350.
Netley, Welsh Military Hospital.—M.O. £400.
Norwich, Norfolk and Norwich Hospital.—H.P. and H.S. £400 each.
Perth, James Murray's Royal Asylum.—Phys.-Superintendent. £800.
Plaistow Fever Hospital.—Asst. M.O. £300.
Sheffield, East End Branch of the Children's Hospital.—H.S. £150.
Stoke-on-Trent County Borough.—Temp. Tuberc. Officer. £350.
Wakefield, Clayton Hospital.—H.S. £250.
Western General Dispensary, Marylebone-road, N.W.—Hon. Oph. S.
York City.—Temp. Tuberc. Officer. £500.

Births, Marriages, and Deaths.

BIRTHS

ALEXANDER.—On Oct. 26th, at a nursing home in Edinburgh, the wife of R. Charles Alexander, M.B., Ch.B., F.R.C.S. Edin., Major, R.A.M.C., B.E.F., of a son.

BURTON.—On Oct. 23rd, at Princes-gate, S.W., the wife of Major C. F. Burton, M.C., R.A.M.C. (S.R.), of a son.

CLIFF HODGES.—On Oct. 19th, at Brompton-avenue, Liverpool, the wife of Major W. Cliff Hodges, M.D. Camb., R.A.M.C. (T.), of a son.

HENDERSON.—On Oct. 24th, at Brighton, the wife of Major A. T. Henderson, C.A.M.C., of a son.

YOUNG.—On Oct. 15th, to Tina, the wife of W. A. Young, B.Sc., M.B., B.S., Captain, R.A.M.C. (S.R.)—a son.

MARRIAGES.

GRIFFITH—SORANZO.—On Oct. 28th, at Palazzo Vidoni, Cremona, Italy, Arthur D. Griffith, M.B., B.S., F.R.C.S., Bt. Major, R.A.M.C. (T.F.), to Aurora, daughter of Conte Tomaso Mocenigo Soranzo and the late Principessa De' Soresina Vidoni, of Cremona.

JOSEPH—HOLMAN-HUNT.—On Oct. 22nd, Captain Henry Michael Joseph, M.C., R.A.M.C., to Gladys, only daughter of the late William Holman-Hunt, O.M., and Mrs. Holman-Hunt.

MARSHALL—PHILIP.—On Oct. 26th, at Mather's Hotel, Dundee, Major Geoffrey Marshall, R.A.M.C. (S.R.), to Belle, youngest daughter of George Philip, Dundee.

WALKER—NOSWORTHY.—On Oct. 24th, at Derby, Ernest H. Walker, M.B., Ch.B. (Manchester), to Alice E. Nosworthy, of Torquay. 34, Charnwood-street, Derby.

DEATHS.

CARTER.—On Oct. 24th, at South Side, Clapham Common, S.W., Robert Brudenell Carter, F.R.C.S., Knight of Justice of the Order of St. John of Jerusalem, late ophthalmic surgeon to St. George's Hospital, aged 90.

DEMETRIADI.—On Oct. 26th, at Southport, Lieutenant-Colonel Louis P. Demetriadi, T.D., R.A.M.C., M.D., F.R.C.S.E., in his fifty-sixth year.

MACKLEY.—On Oct. 29th, Ernest Herbert Alborough Mackley, L.D.S. R.C.S. Eng., of Vermont Dean Park, Bournemouth, aged 46.

PATTEN.—On Oct. 22nd, at Mount Park-road, Ealing, Charles Arthur Patten, L.R.C.P., M.R.C.S., aged 79 years.

SPENSLEY.—On Oct. 23rd, of pneumonia, at the Burdon Military Hospital, Weymouth, Frank Oswald Spensley, Captain, R.A.M.C.

TODD.—On Oct. 13th, at Dordrecht, South Africa, of pneumonia, Dr. C. Gordon Todd (late Captain, South African Medical Corps), younger son of the Rev. James and Mrs. Todd, of Sale, Cheshire.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical News.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—The following candidates have passed the Final Examination and have been granted the diploma L.D.S. R.C.S. Edin.:—

Edward Clive Smith, London; Charles Henry McComb, Belfast; John Sharpe, Piquetberg, South Africa; Albert Donald Barnes, Hereford; and Richard Lisle Eskell, Port Elizabeth, South Africa.

THE Metropolitan Borough of Poplar is supplying, free on application at a number of depôts, electrolytic disinfecting fluid to be used as a mouth-wash and gargle for preventing influenzal infection.

A MEDICAL ASSOCIATION FOR EGYPT.—Hitherto there has been no organisation among medical practitioners in Egypt, and the lack of a representative body has long been felt. A committee has now been appointed to elaborate a scheme for an association or council to look after the interests of the medical profession. The draft project will be submitted to a general meeting of medical men, and if approved by them the Government will be asked to give its formal sanction.

Notes, Short Comments, and Answers to Correspondents.

THE WORK OF THE LONDON PORT SANITARY AUTHORITY.

THE activities of the Sanitary Authority of the Port of London were described by Dr. W. M. Willoughby, medical officer to the port, in a lecture on the Obviation of Ship-borne Infections at the Royal Institute of Public Health on Oct. 23rd. The lecturer prefaced his remarks with a quotation from Gibbon's History which showed that in the reign of Justinian, a time not unfairly comparable with the present, plague was recognised as a ship-borne infection, while the direct infectiousness of the pneumonic form was then appreciated in distinction to the comparative benignity of the bubonic and septicæmic forms. The influence of wars and emigrations on the dispersal of the infection was also known. But it was not, he said, until the concerted work of the Indian Plague Commission from the year 1905 onward showed us the correlation between rodent, flea, and man in the spread of plague that precautionary measures had been effective. Gibbon had remarked that "the wind might diffuse that subtle venom, but unless the atmosphere be previously disposed to its reception the plague would soon expire in the cold or temperate climates of the earth," but the lecturer pointed out that the visitations of the past indicated all too clearly that no reliance was to be placed on the indisposition of England's atmosphere. While the absence of epidemic plague for generations showed the potency of this indisposition as the main factor in our immunity, sanitary measures which did not take the flea and rat into account were incomplete. No poison was more lethal to rats than that of plague, and as the rat population of a vessel was often wiped out during a voyage quarantine had acted as an efficient safeguard against the introduction of the infected rodent. Our immediate ancestors smelt a rat, opened the floor boards and found it, but the present generation was for the most part unfamiliar with the rat, dead or alive. The town-dweller and the rat now lived apart and sweeping epidemics of plague in England were impossible. But dock infections might still occur at points where Eastern trade existed. Prevention consisted in making every storage place for food rat-proof, in removing regularly and rapidly rubbish and discarded foodstuffs, and in a systematic reduction of the number of rats in any district by means of cats, traps, and poison. The inevitable residuum, isolated in small colonies on becoming plague-infected, might be wiped out by the disease without spread of infection. The recent Rat Order of the Ministry of Food had, the lecturer said, followed the correct line in recognising rattiness of premises as a responsibility, monetary and otherwise, of the owner of those premises, and through this Order he hoped that the atmosphere of England might be rendered yet more unreceptive for plague. International agreement laid down certain rules in the case of plague-infected ships, which included the medical inspection of crew and passengers, the disembarkation and isolation of the sick and suspected cases, the disinfection of infected articles and infected quarters, the destruction of rats on board either before or after discharge of cargo, and the observation and surveillance of contents. Dr. Willoughby described the detailed working out of these principles and the special importance of preventing infection by fleas. Other infections were lightly touched upon. In conclusion, the lecturer put forward a plea for a more general education of the public in the rudiments of these relatively simple but fascinating problems.

Dr. G. S. Buchanan spoke of the high degree of efficiency maintained by the London Port Sanitary Authority under circumstances of peculiar difficulty.

COLONIAL HEALTH REPORT.

Ashanti.—The Census of 1911 gave the population as 287,814—141,231 males and 146,583 females—but these figures were admittedly incomplete, and the population has increased since then. The Europeans in 1917 comprised 140 officials, 100 merchants, 122 engaged in the mining industry, and 20 missionaries—total, 382. Coomassie has a population of 24,000, of whom 4000 are described as Ashantis, 4000 as Coast people, 14,000 as North Country people (Hausas, Wangaras, Grunshis, Dagombas, Moshis, &c.), and 2000 as various. The medical report states that the general health of Europeans and natives in 1917 was not so good as in the previous year. There appears to be a steadily increasing tendency for the Ashanti and Hausa elements of the population to come to the Native Hospital for treatment. There was an outbreak of small-pox at Wenchi during the year, which caused 29 deaths out of 164 cases. There was also an epidemic of influenza in Coomassie. Of other diseases the most common were malaria and pulmonary and skin diseases. Of a total number of 140 European officials, with an average of 60 residents, 4 died and 6 were invalided. Among the European non-official population 10 were invalided and 1 died of hæmoglobinuric fever. The sanitation of the towns of Coomassie and Obuasi has been efficiently maintained, if not distinctly improved. A genuine wish for village improvements and the building of better houses is noticeable amongst the Ashantis. The Commissioner of the Western Province writes:—

"The natives of the country thankfully welcomed the visits of the medical officer and his subordinates when engaged in village improvements or employed in prophylactic measures against small-pox, and they brought their children in large numbers to be vaccinated. The alien settlements, however, were suspicious and gave some trouble, particularly the large Wangara population of Wenchi, who are singularly averse to any form of control."

ROYAL ALBERT INSTITUTION FOR DEFECTIVES, LANCASTER.

IT is refreshing in these days of pecuniary strain to receive the report of a charitable institution which has not to complain of financial stringency owing to the war. We have much satisfaction in congratulating the Central Committee of the Royal Albert Institution, Lancaster, on being able to submit in their recently issued fifty-fourth annual report so encouraging a statement as to their financial position. In the auditor's report the following passage occurs: "In Maintenance Account, it is satisfactory to note increases in donations, annual subscriptions, and payments for patients. Interest on invested funds is also higher." Of course, the committee have again to note a progressive increase in the average cost of maintenance, necessitating an increase of the charge for patients sent by public authorities, but not interfering with that for those paid for by necessitous relatives, for whom the original rates of reduced payments are retained. Altogether during the past 50 years the subscribers have elected 2158 inmates dependent either solely or in great part upon the charitable funds so liberally contributed by all classes of the inhabitants of the northern counties. The report concludes with a grateful acknowledgment of the support received in the past, and an aspiration towards increased progress in the future, adumbrating an "ambitious scheme" of enlargement when restrictions occasioned by the war have passed away.

The report of the Medical Superintendent (Dr. W. H. Coupland) for the year ending June 30th, 1918, records the daily average of patients resident as 732 (486 males and 246 females); 59 had been admitted, 39 discharged, and 19 had died, the mortality percentage having been 2·6 on the average number in residence. Eight out of the 19 had died from some form of tuberculous disease and 3 from epilepsy. The general health had been on the whole satisfactory, notwithstanding rationing restrictions in force.

PREVENTION OF VENEREAL.

To the Editor of THE LANCET.

SIR,—In THE LANCET of Sept. 28th it is stated that in a police-court case, under 40 D, a bacteriologist gave evidence to the effect that his examination was negative. Is it not time the College of Physicians, or the Roy. Soc. of Medicine stated definitely whether the absence of spirochete, or of the gonococus, or the Waserman reaction, decided *absolutely* whether the individual concerned is, or is not suffering from syphilis or gonorea? Many think that the absence of the gonocous is not *evidence* that the individual is cured, or that he or she is non-infective, and the same of the Waserman test. It will be a pity if some case come into court when it can be shown that the bacteriological tests can not be relied upon absolutely. Therefore let us have a defenite reliable, and authorative statement.

Liverpool. ROBERT R. RENTOUL.

*** Dr. Rentoul states that he is in favour of phonetic spelling.—ED. L.

"A MEDIÆVAL MEDICAL AUTHOR."

To the Editor of THE LANCET.

SIR,—My attention has just been drawn to your paragraph under this heading in THE LANCET of Sept. 21st. Your correspondent may be interested to know that the French version of John of Burgundy's Tractate is not lost, but exists in the Bibliothèque Nationale, and was published by me in full in the Proceedings of the Royal Society of Medicine, Historical Section, 1916, Vol. IX., page 200. Experts in mediæval French consider, however, that this French version was most probably translated from the Latin, which exists in many MSS. enumerated by me in the same issue of the Proceedings of the Royal Society of Medicine.

On the other hand, the Hebrew text in the Bibliothèque Nationale, Fonds Hébreu MS. 1191, is not a complete translation of the work. It and another Hebrew text, which together do make an almost complete version, have just been published by Mr. Reuben Levy and myself in the "Annals of Medical History," Philadelphia and New York, Vol. I. No. 4.

I am, Sir, yours faithfully,

Oxford, Oct. 25th, 1918. DOROTHEA WARY SINGER.

The Bradshaw Lecture
ON
NEUROSES AND PSYCHOSES OF WAR.

Delivered before the Royal College of Physicians of London on Nov. 7th, 1918.

BY WILLIAM ALDREN TURNER, C.B., M.D.,
TEMPORARY COLONEL, A.M.S.; AND CONSULTING NEUROLOGIST.

MR. PRESIDENT AND FELLOWS OF THE COLLEGE,—Under the terms of the lectureship, the Bradshaw lecturer is free to promote the interests of medicine by a discussion of any relevant subject. I have undertaken, therefore, to bring to your notice a short account of the neuroses and psychoses of war, confining my remarks especially to the neuroses more directly attributable to the stress of active warfare and what has been popularly called "shell shock." Without this limitation it would have been necessary to have begun with a description of the neuroses and psychoses which occur during the training of the recruit. This, indeed, might be a fruitful introduction to the subject, as the nervous and mental disabilities of this period are instructive in relation to those of active warfare. During the early months of the war, under the voluntary system of recruitment, neurasthenic symptoms were not uncommon in association with conflicts in the minds of conscientious men, who were torn between duty to their country and their personal feelings, opinions, and habits.

NEUROSES AND PSYCHOSES OF TRAINING.

In more recent times, under compulsory service, many men have entered the army who are constitutionally and by upbringing and education unable to adjust their outlook to service conditions. In other words, the young soldier becomes neurasthenic owing to a failure of adaptation to a continued emotional cause and the struggle to bring about such adaptation (Dejerine). This failure may take the form of either a nervous or a mental disability.

In the neurasthenic type the symptoms are those well known in the neurasthenia of civil life—fatiguability, digestive disturbances, vague myalgic pains, and hypochondriacal feelings. This is a nervous reaction to camp life, and is frequently accompanied by fears and dreads in anticipation of what may happen when the soldier proceeds on active service, such as death or serious incapacitating wounds. A large number of these men are constitutional neurasthenics, and have suffered from a nervous condition previous to joining the army.[1]

Those who have had opportunities of working in the mental war hospitals know how frequently young soldiers, especially when below the normal standard of mental development, are prone to mental breakdown during the early months of training, and how readily any latent morbid or abnormal trend may be brought quickly to the surface under the stress of camp life and military discipline. (Henderson.[2])

PSYCHOSES OF WAR.

Although a large number of recruits with definitely neuropathic or psychopathic tendencies may pass through the period of training successfully, there remains a liability to breakdown when the soldier finds himself under the stress and strain of active service. Here the emotional causes are obviously more potent and more continuous, and the psychoses are the reactions to a situation which cannot be adequately met. Although the statistics from the mental war hospitals differ to some extent, one is struck by the numbers of mental defectives and of those with known psychopathic heredity or disposition admitted as patients. Approximately 10 per cent. of the patients coming into the mental war hospitals from overseas have had a previous attack of certified insanity.

A confusional psychosis is probably the most common type of mental reaction observed in soldiers coming from overseas. In many cases it is superimposed upon a foundation of feeble-mindedness. In others it forms the basic reaction and is attributable to a cerebral commotion, shell shock, or psychical trauma occurring in soldiers with a psychopathic inheritance. In both these types the prognosis is good, the duration of the confused state being relatively short and lasting from a few days to several weeks.

There is another variety in which a confusional psychosis is the early phase or the onset of an underlying and more deeply rooted disorder, such as dementia præcox. Eager[3] has recorded that amongst the large number of cases admitted to the Lord Derby War Hospital 28 per cent. belonged to the manic-depressive group, 19 per cent. were classified as mental deficiency and delusional insanity respectively, and 8 per cent. as dementia præcox.

Although the study of mental reactions attributable to stress of campaign is of great psychiatric interest,[4] I do not propose to continue the subject further, but ask you to accompany me to a neurological centre in France, where we shall have an opportunity of observing some types of cases illustrative of the neuroses of war.

CLINICAL TYPES OF WAR NEUROSES.

We would see amongst the patients men who had been sufferers from a war neurosis on previous occasions, and who had been returned to duty.

We would see also young and inexperienced soldiers who had given way to fear or alarm at their first experience of bombardment. Some of them would show the acute symptoms of fear in dilatation of the pupils, staring eyes, rapid action of heart, and sweating. Others would give the impression of having lost, at all events for the time, their self-respect and self-confidence. A few of them exhibit rhythmical tremors, which had, no doubt, been involuntary and irrepressible at first, but which were now within the range of voluntary control and susceptible of relief by distraction, persuasion, and encouragement.

There would also be patients suffering from fatigue and nervous exhaustion, requiring rest in order to restore them to duty. The symptoms complained of by these patients, in addition to a sense of weariness, consist of irritability and jumpiness, with difficulty in concentrating attention. Some would probably say that their sleep was disturbed by unpleasant dreams connected with their duties, and that they had difficulty in falling off to sleep and might waken with a start. Others might complain of palpitation, giddiness, breathlessness, and a feeling of oppression or anxiety in the region of the heart.

Our attention would be called to another class of case in which the symptoms are those of an anxiety neurosis. The patients are commonly young officers. A frequent history is that after he has been abroad for several weeks or months the officer begins to sleep badly and loses appetite. Worry and anxiety follow on this; he loses confidence in himself and thinks that he is incapable of doing his duty adequately. He becomes shaky, unduly emotional, and finds that his sleep is disturbed by nightmares referring to his experience of trench warfare. Even the waking hours may be distressful from the acute recollection of these experiences intruding into his memory. Headache, mental depression, and a fine tremor may accompany these symptoms, but the reflexes are normal, the tongue is clean, and the pulse of normal frequency. In the more exaggerated types fears as to his sanity, as to his ability to "carry on," as to whether his comrades may think he is a coward, begin to obsess him. This condition may continue, and the soldier perseveres with his work until a commotional shock, an upsetting experience, or bad news from home precipitates an incapacitating disability and he is sent to hospital.

On our progress through the wards our attention would be called to a class of case presenting very definite objective signs, such as we are accustomed to see more commonly in the neurological hospitals at home. Probably the largest class would show speech defects, such as mutism, deaf-mutism, aphonia, and stuttering. Others would present diverse types of tremor and tic-like movements. We would see various forms of paralysis, especially of the lower limbs, with disturbances of gait of the astasic-abasic type. We might see one or more cases of "bent back."

Examination would reveal the fact that these symptoms were of a functional or hysterical character, and that many of the patients had been admitted to hospital in a state of stupor following a shell explosion or burial.

STUPOR, DELIRIUM, AND AMNESIA.

The cases forming the next group are especially interesting, as they demonstrate what may be regarded as the most acute expression of psychoneurotic symptoms, due to fear, horror, and profound emotional or commotional causes. Stupor and delirium are the outstanding features, and of the two types one is distinguished by torpor or cerebral inactivity, the other by what has been called "visionary" or "oneiric" delirium. The symptoms of the stupor type are quite distinctive. In

the more severe class of case the patient is entirely unconscious of his surroundings; he lies motionless in bed and makes no reply to questions; his eyes show no recognition of what is before them; all the usual tests applied with the object of arresting his attention fail to provoke a response. A close examination reveals in many cases some rigidity of the limbs of the catatonic type. The deep reflexes may be normal or exaggerated; the pupil light reflex may be impaired or lost; the plantar response may be flexor or abolished. Urine may be passed normally, or catherisation may be necessary for a day or two. Swallowing is effected usually without difficulty.

In milder cases stupor is less profound. The patients may carry out simple actions, but in a slow and hesitating way. They present a dazed or confused appearance, are startled easily, and take little or no notice of what is going on around them. In the other type the delirium is accompanied by gestures. These patients would appear to be living as in a dream through a recent terrifying experience. When information has been obtained as to the onset of the symptoms it has been found to be connected with a psychical shock, such as the mutilation or burial of a comrade or friend from shell explosion.

The duration of the stupor varies. In some instances the intensity of the stupor may have passed away before admission to hospital. It lasts usually from a few hours to several days and may pass off suddenly or gradually. This symptom is found mainly in young soldiers.

With the disappearance of the stupor the soldier may find that he is mute, deaf, paralysed, or unable to walk without assistance, the subject of a tremor, or, very commonly, the victim of an anxiety condition in which intense headache, battle dreams, insomnia, vertigo, lack of mental concentration, and fatigue are prominent symptoms. The memory for the stupor period and probably also for some days antecedent to it is obliterated. In the milder cases it is merely confused and uncertain. Cases may be found in which the memory of the whole life antecedent to the shock has been wiped out; and there are other cases in which the memory of the specific emotional episode which precipitated the stupor may be retained, though that of the subsequent days is abolished. The amnesia of cerebral concussion is probably more profound than in the emotional cases and is of both retrograde and anterograde type. It is to this period of stupor and amnesia that the soldier applies the term "loss of consciousness" or "loss of memory."

The majority of the cases of stupor and delirium are examples of psychoneurotic mental states, attributable to fear and horror, but phenomena essentially identical to them may be found in men who have been exposed to a cerebral concussion or commotion.

ORGANIC AND FUNCTIONAL CONDITIONS.

At all times there may be a difficulty in the differential diagnosis of the concussion from the so-called emotional cases, but such diagnosis is more easily effected the earlier the patient is brought under observation. A careful neurological examination of men who have been exposed to the effects of shell or mine explosion or who have been buried and are suffering from loss of consciousness, stupor, mental confusion, delirium, or paralysis would in some instances reveal the physical signs of minor structural lesions of the brain or spinal cord.

In the writings of the earlier observers on this subject, and in some at the present time, there is a tendency to attribute many of the phenomena of shell shock and the war neuroses to physical causes, such as concussion, fatigue, or gas-poisoning, and perhaps to ignore, or at all events underestimate, the influence of the psychical factor. A school of the French neurologists in particular has laid stress upon the importance of "cerebral commotion" in the causation of the psychoneuroses of war.

The modern school of psycho-pathologists, on the other hand, may incline too much in the contrary direction, and claim all the symptoms of the war neuroses to be of psychogenetic origin. This school maintains that the neuroses of war arise from an inability on the part of the soldier to react to his environment; in other words, they are brought about by a failure of psychological adaptation and to the repression of one of the conflicting emotions which arise therefrom.

In many of the published records of cases of war neuroses and shell shock the distinction has not been drawn with sufficient clearness between those symptoms which arise in consequence of physical and psychical causes respectively; nor is this altogether an easy matter, even when each case has been examined neurologically in the earliest stages after the shell explosion.

We may now proceed to examine in fuller detail the origin of the neuroses of war, and in particular their relation to the sudden incapacitating agency of "shell shock."

CONCUSSION SHOCK.

Some of the French neurologists draw a distinction between direct and indirect concussion.[5] In the former the symptoms are those of structural lesions of the central nervous system. In the latter there is no visible external injury, but a "cerebral commotion" is produced indirectly by exposure to the forces generated by the explosion of powerful shells through atmospheric vibrations transmitted to the nervous tissues by the cerebro-spinal fluid.

The immediate clinical effect upon the soldier of cerebral commotion due to the forces generated by the explosion of shell or mine is a loss of consciousness which may last from a few minutes to several days. This may give place to a partial loss or "twilight state" of consciousness, with which may be associated mental confusion or a "visionary" delirium resembling that which has been described.

A detailed neurological examination, therefore, is necessary in quite the earliest stages of all cases in order to determine the existence or otherwise of structural changes in the central nervous system.

We are indebted more especially to the French neurologists,[7] working in the neurological centres of the French Armies, for observations on this point. The following have been observed in the earliest stages of shock: muscular relaxation and hypotonia, impairment or abolition of the deep reflexes, the presence of an extensor plantar response, retention of urine, inequality of the pupils, and impairment of the light reflex, hæmorrhages into or rupture of the retina, and voltaic vertigo. The examination of the cerebro-spinal fluid during the first two or three days following the shock may exhibit blood staining, raised pressure, increase of the albumin content, and sometimes a lymphocytosis.

These objective signs may be quite transitory, and disappear rapidly within a few days, so that when the patient is re-examined after a short interval, no evidence of their existence is detected; but the presence of other symptoms may be observed. It is most unlikely that concussion, pure and simple, unaccompanied by any emotional element, gives rise to psychoneurotic symptoms. There is, however, a class of case probably belonging to the suggestion hysterias in which early organic symptoms may be succeeded by those of a hysterical character.

"TRAUMATIC NEUROSIS."

It would appear, therefore, as if minor recoverable changes of a structural character due to "commotion" may play an indirect part through suggestion and association in the pathogenesis of those symptoms, which disappear under persuasion. This leads to the subject of "traumatic neurosis," the original idea of which was that the nervous and psychical symptoms were dependent upon organic lesions of the brain arising in consequence of the trauma. A conception more in harmony with current psychological doctrine attributes the symptoms of the neurosis to psychical causes. Farrar [9] has thus expressed it:—

> "The injury of nervous tissue is not necessarily the cause of any possible manifestations which may follow, but it may serve as the starting point of certain trains of association which need never be fully in the consciousness of the patient, but which nevertheless eventuate in the developed fixed neurosis, with all its psychical, neurological, and somatic phenomena."

The chronic symptoms of the fixed neurosis or sequelæ of concussion are, on the neurological side, persistent and often severe headache, photophobia, hyperæsthesia to sounds, vertigo associated with labyrinthine hyperæsthesia, insomnia, and battle dreams. On the psychological side, loss or perversion of memory, irritability, loss of self-confidence, defective concentration and slowness of thought, over-emotivity, depression, anxiety, and even melancholia. Amongst these symptoms are several which are more characteristic of the anxiety neurosis, such as over-emotivity, "terror dreams," anxiety and depression. It is unlikely that concussion gives rise to anxiety unless this neurosis was in process of development at the time of the shock. Concussion, therefore, happening to soldiers in whom neurotic symptoms are already present, may cause a sudden accentuation of the anxiety picture.

Although the symptoms mentioned may scarcely be regarded as peculiar to cerebral commotion in the orthodox sense, they are characteristic of quite a numerous class of patients in the war hospitals at home. The course of this disability is always protracted and improvement may not take place until after many months. From the purely military standpoint the class is important, as a relapse almost invariably follows a return to active service. Moreover, it is always a difficult matter to determine just the point where the neurosis merges into a subconscious or partially conscious exaggeration of symptoms. So many influences combine to favour exaggeration or prolongation of symptoms in soldiers, such as return to further service, permanent incapacity, and considerations over pensions, that there is no question in the whole range of psycho-neurotic disorders upon which medical officers have greater difficulty in giving a decision. But malingering in the sense of being a conscious and reasoned simulation or creation of a pathological picture for the purpose of deceit is rare in our military neurological hospitals.

FAILURE OF PSYCHOLOGICAL ADAPTATION.

Contemporary psycho-pathologists maintain that all neuroses are "reactive" disorders—that is to say, they are the consequences of a failure of psychological adaptation or readjustment to environment. Associated with the process of readjustment is repression, which, as Rivers[11] says, is not in itself harmful, but only under conditions in which it fails to adapt the individual to his surroundings.

The psychological history of every individual will reveal how far he has been able to adapt his mental outlook to the ordinary and accidental circumstances of his life.

On entering the Army, as we have seen, men may break down owing to a failure to react normally and to readjust themselves to the conditions of military service, discipline, and training.

On entering the zone of the active operations of war circumstances calling for adaptation and readjustment at once present themselves, and it is remarkable how large is the number of men who are able within a very short time to react physiologically and maintain their nervous health for long periods under the exacting conditions which characterise modern warfare. It is not easy, for various reasons, to estimate the number of men admitted to hospital on account of war neuroses and the effects of shell shock, but an approximate estimate puts the number at from 5 to 6 per cent. of the total sick transferred to the hospitals at home.

It is well known that soldiers wounded physically do not as a rule suffer from shell shock, although no doubt they have been exposed to the effects of shell or mine explosion just as have the unwounded. Wiltshire[12] explains the immunity of the wounded on the ground that a physical wound neutralises the action of the psychical causes of shell shock, but it is more likely that the somatic wound, being the ideal form of relief, is to the soldier the fulfilment of his wish to get away from an intolerable situation. Both anxiety and hysterical symptoms may appear later on, when the wound is healed. In all warfare, but especially in the trench form, which has been a special feature in the present war, numerous factors are at work to impair the soldier's resistance.

PRODROMATA OF "SHELL SHOCK."

It has been stated by one writer on the subject (Forsyth[13]) that the situation derives its psychical importance from the fact that it involves the risk of death.

Core,[14] in a suggestive paper on "Instinct Distortion or War Neurosis," points out that in modern warfare men are daily put into positions of imminent danger; the danger to life under certain conditions of military duty may be so great as to render death a practical certainty.

MacCurdy,[10] who has written an instructive paper on the war neuroses, gives a graphic account of the development of the anxiety states, which are amongst the commonest of the war neuroses. This writer has referred in detail to the mental conflict in soldiers on active service, and officers in particular, between desire to continue on duty and the repression of an increasing feeling of incapacity and apprehension. The soldier becomes fatigued and his adaptation becomes weakened and finally lost. He feels every day more acutely sensitive of the horrors around him. He becomes apprehensive and his courage is forced. He begins to feel ashamed that he may be regarded as a coward by his comrades. He grows mentally and nervously more unstable. He regards as a weakness the thought of going sick. He fears that he may not be able to hide his fear.

Under the influence of mental conflicts such as these the soldier may resort to reckless and daring deeds. He becomes hypersensitive, irritable and jumpy, and his sleep may be disturbed by dreams connected with his duties. Eventually the idea develops of how he can escape from an unbearable situation, and sometimes with this the desire for death and thoughts of suicide.

When this degree of mental anxiety and depression has been reached, and in many cases long before, any shock may precipitate a breakdown. Amongst such shocks may be horrible sights, partial burial in consequence of shell or mine explosion, an unusually dangerous situation, a serious disappointment or bad news from home, but most common of all a cerebral concussion or commotion from shell explosion. The effect of one or other of these traumata, but especially the last, is the onset of a stupor, a delirium, or an amnesic "fugue."

PSYCHOLOGICAL CONTENT OF STUPOR.

The acute or major symptoms of the war neuroses follow upon the shell explosion or other precipitating cause.

The onset of these symptoms occurs usually under two conditions. First, they are observed as the soldier recovers from a stupor or amnesia of the onset and duration of which he has no recollection. In some cases, however, a brief interval may elapse between the shell explosion and the loss of consciousness, in which an emotion of intense fear or horror may be active.

Secondly, the symptoms may develop after an interval of variable duration from the shock, during which the soldier may have attempted to "carry on," may have been found wandering behind the lines in a somnambulistic "fugue," or may have been able to find his way back, alone or assisted, to a regimental dressing-station or ambulance. In this last event the memory of what has occurred is retained, although the mental perspective may be blurred, and the man may state that he "fainted" or was momentarily stunned at the time of the shock. These patients may be able to describe the circumstances of the shell explosion or give a vivid account of the horrible sights which they had seen.

As already described, the shell shock is the coping-stone or precipitating agent in a series of mental pre-occupations which may have troubled the soldier for weeks or months. It will be of interest, therefore, to analyse, so far as this is possible, just what is the psychological content of the stupor, as the effect of it upon the soldier's mind is such that he traces the development of his subsequent symptoms mainly to the "loss of consciousness" or "loss of memory" which he associates with the shock. In some cases stupor-amnesia is of "dynamic" nature, arising from a cerebral concussion or commotion. In other cases it is "functional" and of a psychical character, but it is not unlikely that the latter may emerge from an original transient commotional loss of consciousness.

W. Brown,[15] who was for some months in medical charge of a neurological centre in France, says that an examination of many of these cases under hypnosis shows that there is a dissociation or splitting of the personality rather than a true loss of consciousness. He is of opinion that the stupor-amnesic phase corresponds to a period of subconscious emotional development dominated by fear and not to the working merely of suggestion. Acting on this hypothesis, he has treated his patients by means of light hypnosis, during which they go through their trench experiences, and in this way "work off" the suppressed emotion. It is this which, in his opinion, brings about the return of the power of speech, and not direct suggestion.

Myers,[16] who also has had favourable opportunities of studying cases of shell shock in the stupor phase, states that under hypnosis these men often become excited, and not infrequently show clear evidence of living again through scenes which come vividly to their minds. In his view, dissociation arising from inhibition is the fundamental cause of the effects of shell shock.

MUTISM AND ASTASIA-ABASIA.

It has been mentioned already that certain objective functional symptoms may be observed as the soldier emerges from the stupor which follows a shell concussion or psychical shock. Of these the most important are mutism, deaf-mutism, and the minor speech defects—aphonia and stuttering. Indeed, mutism and deaf-mutism are prominent symptoms during the period of stupor, and are attributable

to the inhibiting influence of the fear or horror which underlies the stupor.

Mutism is accompanied frequently in the earlier stages by other symptoms of the neurosis, such as headache, tremors, twitchings of the limbs, and insomnia; and, apparently as a kind of counterpoise to the dumbness, a certain fluency of expression in writing is not uncommon.

Myers, who has made a special study of mutism in relation to shell shock, states that in nearly every instance mutism is closely dependent on some form of stupor and is a relic of that condition after it has passed off. As he regards stupor as a state of functional inhibition, it is not difficult to understand that inhibition should disappear last in the case of hearing and speech, which are the two main channels of intercourse with others.

Another and less common motor disability resulting directly or indirectly from the effects of shell shock is astasia-abasia, in which on attempts at walking the limbs are incapable of action, in spite of obvious effort to move them. This paraplegic disorder may be accompanied by clonic tremor. It is observed in many atypical forms, some of which resemble the disordered gait accompanying organic disorders of the nervous system.

A variety of this disability is accompanied by anxiety, in which the patient is obsessed by a fear that he is unable to walk; he clutches at any support; he can only be made to take a single step forward, and if he puts one leg forward he quickly draws it back, certain that he is about to fall.

These disabilities of speech and gait, if left untreated in the early stages, may become "habits" and join the other functional disorders described under hysteria as unconsciously developed "defence mechanisms."

ANXIETY AND DEPRESSION SYMPTOMS.

The anxiety neurosis and anxiety depression are amongst the most common symptoms of the war neuroses. They may occur alone or in association with mutism and paralytic symptoms. We have already seen the development of an anxiety neurosis prior to the receipt of the psychical shock or cerebral commotion. The effect of these agents is to determine a more acute development of symptoms, which incapacitate the soldier and render him temporarily unfit for duty. The outstanding symptom of the anxiety neurosis is the recurrence of terrifying nightmares or "terror dreams" which torture the patient during sleep, and in consequence add to his troubles a fear of going to sleep.

Mott,[17] who has made a study of them, says that although the soldier sometimes may have no conscious recollection of the dream he may wake up suddenly in terror, bathed in perspiration, or he may have been heard to shout in his sleep and seem to go through a pantomime of fighting with bombs, rifle, and bayonet.

The patient's progress towards recovery may be estimated largely by the degree and frequency of his dreams. The first sign of recovery from the neurosis is when the dreams no longer wake the patient, although he may remember that he has had them. As the patient continues to improve the element of fear disappears from his waking life and in the course of time from the dreams. (Core.)

The prominent mental symptom of the anxiety neurosis is depression, coloured by underlying fears and dreads. This depression is not continuous, nor is it of the negative type characteristic of the melancholic. It may be revealed outwardly by a drawn and anxious facial expression, and a lack of interest or of desire for companionship. There are periods when the patient is relatively free from anxiety, but such spells of intermission may be broken by apparently causeless waves of depression, accompanied by anxiety and apprehension, and often associated with the intrusion into consciousness of the memory of a particular and unpleasant incident of war experience.

Rivers has pointed out that many of the most trying and distressing symptoms of war neuroses are not the direct result of the strain and shock of warfare, but are due to the attempts to banish from the mind distressing memories or painful affective states which have come into being as the result of war experience.

Rows[18] has shown that of equal and perhaps greater importance in the maintenance of the anxiety symptoms in soldiers, after the more acute or immediate symptoms of the war shock have passed away, are the memories of experiences in earlier life, with which a strong emotional tone is connected. These memories may be revived in dreams, which are often added to the war dreams; or they may be associated with delusions and hallucinations of hearing, often of a persecutory type.

Cases such as those last mentioned, and they are not so uncommon as might be supposed, require prolonged mental analysis and much patience for their elucidation. If the patient can be brought to understand the nature of his trouble, to face it, and to recognise in it simply a memory of the past, the anxiety will lessen and eventually disappear.

An objective sign of the anxiety neurosis observed at the outset and subsequently is profound loss of body weight. This may occur to a remarkable extent, up to as much as one or two stones. The recovery of the weight is coincident with the disappearance of anxiety and general improvement in the patient's health. Lowered blood pressure and an unusual degree of fatigue on physical effort are associated phenomena.

A number of those who suffer from the milder forms of the anxiety neurosis, coming home from overseas, recover in a relatively short time, varying from a few weeks to three or four months, under conditions entailing rest, quiet, and attention to sleep. About an equal number require special psycho-therapeutic attention before they find relief from their more persistent symptoms. But if the mental disorder has become fixed and systematised the difficulties may be great, and recovery will not always take place.

SYMPTOMS IN OFFICERS AND MEN.

It is a common observation that symptoms of anxiety and so-called neurasthenia are more common in officers, and that the more objective symptoms of hysteria—mutism, contractures, paralysis, astasia-abasia—are more frequently observed in men. In a general way this is true, but a combination of anxiety-depression and gross hysterical symptoms is by no means uncommon amongst men in the ranks.

Several explanations of this difference have been offered, but the most likely reason is found in the position of greater responsibility in which the officer is placed, and to the mental struggle which he undergoes in order to banish from his mind doubtings as to his adequacy or competency. The statement has been made that the mental background of hysteria in the men is an attitude of antagonism to the fighting, accompanied by an idea of release from an unbearable situation (McCurdy). This release may be obtained through several agencies, but a slight concussion, a psychical shock, partial burial, a minor and not necessarily incapacitating wound, an accident or an illness, may be sufficient.

HYSTERIA IN SOLDIERS.

The functional disorders of speech have been given separate mention, as mutism is due to dissociation arising from inhibition or subconscious emotional development during stupor. Interference with consciousness, indeed, appears to be the crucial test of so-called "shell shock."

In Dejerine's[19] view emotion alone is much more powerful than suggestion in creating symptoms by dissociation, although he admits the secondary rôle of suggestion in the persistence of hysterical symptoms.

Babinski,[20] on the other hand, holds that suggestion plays the essential part in the production of hysterical phenomena, and that the neurology of the war has strengthened in his mind the idea of the indispensable rôle of suggestion in their production.

It has been observed by all workers in the neurology of the war that hysterical manifestations are less frequent and less striking in the front lines. It is when the soldier is removed to calmer surroundings away from danger, such as a casualty clearing station, that the psycho-neurotic condition comes to light. If the patient is not treated suitably at this period the emotion which causes the symptoms becomes fixed and more deeply rooted the older its inception. Hence hysterical paralyses, contractures, disorders of speech, of hearing, of gait, and of vision are more numerous in the base hospitals, and especially in those at home.

Local trauma, such as a minor gunshot wound when applied to any part of the body, may produce a psycho-neurotic disturbance in a predisposed person. It acts through auto-suggestion, as well as through emotion, in that it creates the idea of an organic disorder and constitutes the agent which fixes the neuropathic condition.

The onset of local pain also, with or without bruising of the part, may act as a determinant of a functional disorder. Following upon a fall or being thrown against some object in consequence of shell explosion or burial, but without any

loss of consciousness, the soldier may complain of a severe pain in the back, which may be followed by loss of power in the legs of a functional character. In other cases the pain may interfere with extension of the spine. In order to relieve the pain an attitude of flexion of the body is assumed, and the condition known as "bent back" or camptocormia is evolved. This is primarily an antalgic posture, which may eventually lead to a contracture of the muscles of the trunk of hysterical character.

Hysterical contractures of the hand or foot are frequently the outcome of a wound of the arm or leg, with or without implication of the peripheral nerves of the limb. The exciting cause may be anything from a slight and superficial abrasion to a penetrating gunshot or shrapnel wound. Sometimes the contracture instantaneously follows the receipt of the wound, but in the majority of cases it would appear to be the outcome of suggestion following immobilisation of the limb in a sling, splint, or other mechanical apparatus.

It is not exceptional to find paralyses and contractures preceded by more or less vague pains in the joints of limbs which have been bruised. These pains may be the origin of hysterical paralyses or contractures, apparently of spontaneous origin, and which persist long after the pain has disappeared. Hysterical disorders, moreover, may develop while the soldier is in hospital suffering from a medical or surgical disability, connected or not with war experience, such as trench feet or appendicitis.

Most of the war hysterias, if allowed to become habitual, are eventually "defence mechanisms," developed unconsciously, but persisting as reactions against various contingencies, of which the chief is a desire not to return to the firing-line or, indeed, to any form of active warfare.

Any suggestion of organic disease on the part of the medical officer, on whose opinion the soldier rightly lays great stress, should be carefully avoided, as the latter is always ready to accept and retain in his mind any suggestion that he is not likely to recover.

TREATMENT OF WAR NEUROSES.

It is a matter of practical experience that the hysterical symptoms of the soldier can be cured rapidly and effectively by a well-directed and convincing psychotherapy, consisting of suggestion, persuasion, and re-education. On the contrary, their duration and persistence may be prolonged indefinitely by repeated changes from one hospital to another and by unsuitable and misguided methods, by which is meant a therapy promoted to suggest to the patient that he is suffering from a serious disability of organic nature, especially when this treatment is carried out in an atmosphere of sympathy and hero-worship. Treatment given at spas, where great attention is paid to electrotherapy, balneotherapy, and massage, undoubtedly tends to fix the neurosis in the patient's consciousness.

It is universally admitted that the sooner soldier patients suffering from any form of functional nervous disorder are submitted to a therapy in accordance with the psychogenetic origin of their symptoms the more rapid and satisfactory is the cure.

PROVISION FOR TREATMENT OF THE NEUROSES IN THE ARMY.

Early in 1915, in consequence of the large number of cases of this character requiring expert diagnosis and treatment, the Director-General of the Army Medical Service established neurological sections in all the general Territorial hospitals in the United Kingdom, under the care and direction of physicians who had special knowledge of, and experience in, diseases of the nervous system. A limited number of special hospitals were also set up for patients suffering from the more obviously psychical effects of shell shock and the war neuroses, and who were not suitable for treatment in general hospitals.[22]

As time went on fuller knowledge and larger experience of these cases were acquired from a study of them in the special hospitals. It became evident that the multiform symptoms of the war neuroses and minor psychical disturbances following stress and strain of the campaign were of psychogenetic origin, and that a knowledge of normal and abnormal psychology and of mental disorders was essential in order to obtain correct insight into diagnosis and skill in treatment.

In consequence a larger measure of success attended the treatment of those patients in special than in general hospitals, where the essential conditions of treatment were not available. Numbers of soldiers, therefore, were being discharged from the service on account of functional nervous disorders of a kind curable under proper conditions of treatment. In order to remedy this state of affairs it was necessary largely to increase the number of special hospitals, to divert as far as this could be done the admission of functional cases from the general to the special hospitals, and to make provision for the training of special medical officers. Recommendations based on these principles were laid before the Director-General at a conference of neurologists and psychologists at the War Office in the autumn of 1917, and have now largely been carried into effect.

Training of Special Medical Officers.

In order to meet the needs of the special hospitals a training centre for medical officers was established in connexion with the Maghull Military Hospital, under the direction of Lieutenant-Colonel R. G. Rows, who has done so much towards developing the psychological treatment of the war neuroses. In addition to acquiring a sound clinical knowledge of these disorders medical officers are grounded in the principles of psychology and psycho-pathology. I mention this especially, as it is the first and at present the only school of clinical psycho-pathology in this country, although other training centres are now being established. It is the hope of those who are interested in this branch of medicine that so favourable an opportunity of continuing a school of this character should not be allowed to lapse, and that something should be done during the period of reconstruction after the war to establish on a permanent basis and for the benefit of the civilian patients one or more institutions similar to that which has been founded to meet the urgent claims of the soldier.

Principles of Treatment of the War Neuroses.

There would appear to be general agreement upon the value of the segregation of soldiers suffering from the neuroses of war and three to four years' experience has justified the principle. It is essential that these patients, when segregated, should be under specially trained medical officers and that "an atmosphere of cure" should pervade the special hospital. The great value of segregation is that all patients may be studied individually and all agents determining causation, exaggeration or prolongation of symptoms may be sought out and eliminated. There is no evidence that in properly conducted hospitals these patients imitate each others' tremors or abnormal gaits, while it is well known that in general hospitals the eccentricities of conduct and behaviour of the hysterical patients make them objects of curiosity and often of humour to the other patients.

It has long been recognised that the sooner the patients are brought under skilled treatment the more rapid and satrsfactory is the cure. By these means the symptoms which in the early stages are removable and "fluid" are prevented from becoming fixed and a "habit" established. The French Military Medical Service recognised this early in the war and established neurological centres in the zones of their armies. In consequence of the success attending the treatment of the war neuroses in these centres similar centres were established in the areas of the British armies in the winter of 1916–17.

A large number of cases of war neuroses in the early stages of their disability derive great benefit from a modified rest cure. In the later or "habit" stages a judicious combination of suitably directed psychotherapy and selected occupation, according to the mental and physical fitness of the soldier, gives the most satisfactory results. Occupation further supplies the best means of grading the soldier when the time arrives for his discharge from hospital to duty.

FACTORY AND WORKSHOP CONDITIONS AND THE PREVALENCE OF PULMONARY PHTHISIS:

THE NEED FOR AN INDUSTRIAL HEALTH SERVICE.

BY BENJAMIN MOORE, D.Sc., F.R.S.

THE recent inspiring speech of the Prime Minister, dealing with industrial health conditions after the war, has led the civilised world to hope for the dawn of a new era, in which all the resources of science and research will be as strenuously employed in devising means for the preservation of life, health, and happiness as they now are in the invention of instruments of destruction and the production of untold suffering and human misery. The recent Census of physical fitness for military service has, moreover, revealed appalling shortcomings in the physique and health of our nation, which possesses a well-deserved repute as one of the healthiest and most hygienic of all civilised peoples.

This being the case, it is little wonder that the attention of both statesmen and people is turned with one accord to the urgent problem of applying the knowledge of science to the eradication of disease and the evolution of a physically fitter race. If disease caused, as is so commonly erroneously supposed to be the case, an elimination of the unfit, then the recent Census ought to indicate that Great Britain would soon be inhabited by a superbly fit race, for it contains assuredly a sufficient number of people who have been attacked or are now suffering from the ravage of disease, hitherto unsuspected, and unrevealed by our present methods of attempting to bring the doctor in touch with the patient.

But disease is unfortunately no eliminator of the unfit, and never was; it is merely a blind destroyer, like the mechanism of war, and its bullets fall like rain upon the just and the unjust, the fit and the unfit, and maim and slay both alike indiscriminately. The fittest individual to resist and survive in an unhealthy environment may not be the fittest to survive in a healthy environment, and it is the latter, not the former, that is required for the higher purposes of the best civilisation.

Phthisis has deprived the human race of some of its greatest geniuses at the period of their maximum productivity, and the loss to civilisation has been incalculable. At the same time that this disease has robbed the world of men and women of the highest mentality there exists not an iota of proof that the destruction of the millions who have succumbed to it has by one jot improved the physique of any race. Rather by the misery and semi-starvation which have followed the decease of parents the physique of the race has deteriorated, and if tuberculosis could be eliminated the general standard would improve, for susceptibility to the *Bacillus tuberculosis* by no means connotes general physical debility.

Incidence of Phthisis.

During the past few years I have been engaged in a series of efforts to study in how far the rate of incidence of phthisis in the different sections of the community varies with the nature of the employment, and the strain of living conditions, such as indoor and outdoor work, and prolonged or irregular hours of employment. For the purposes of this inquiry I have made many observations of the actual conditions of work in those occupations most heavily hit by this disease during prolonged visits to workshops, and investigations of workmen in such crafts after long periods of overtime; secondly, I have studied statistically and individually the insurance cards since the beginning of operation of the National Health Insurance Act; and, lastly, I have investigated by means of the returns of the Registrar-General the effects of the aggregation in workshops of men engaged upon urban types of labour as distinct from the effects of urban housing as shown by the incidence amongst the female urban populations.

The results of the last-named type of inquiry are so striking and demonstrate so clearly the effects of urban types of employment in increasing the prevalence of phthisis that they deserve some brief description at a time when it is becoming so essential to conserve the young adult male population. The other methods mentioned will only be used incidentally to point out methods by which the evil may be minimised.

It is fairly well known that phthisis destroys more lives amongst males than amongst females, it is less known that this applies only to urban conditions of life and that the exact reverse holds for rural dwellers; nor is it appreciated that the greater death-rate amongst males is entirely due to the modern conditions of factory and workshop life, and did not exist 70 years ago. Again, up to the period when employment begins, or at least began before the war—that is to say, the fourteenth or fifteenth year of life—the death-rate of females from phthisis is about 50 per cent. greater than that of males, and between the tenth and fifteenth years, whether in town or country, the death-rate from phthisis of girls is almost double that of boys.

Until the twentieth year is reached the mortality in both sexes is considerably greater in rural districts than in urban districts, between the twentieth and thirtieth years the conditions become reversed, and after the thirtieth year there commences an enormous preponderance of the disease amongst urban males which is not shared by urban females, and no such disparity is observable between rural males and rural females.

Economic Importance of Mortality from Phthisis.

The enormous importance of these variations may be appreciated from a study of the accompanying graphs, in which the death-rates have been calculated and plotted at different age-periods from the figures given in the last published decennial report of the Registrar-General for the decennium 1891–1900.

It scarcely strikes the imagination when flat rates at all ages for males and females in town and country are given, such, for example, as that, per million living, there die annually 1750 urban males, 1250 urban females, 1317 rural males, and 1240 rural females. But when the death-rates are plotted graphically and it becomes apparent that nearly all the differences lie in the main working period of life between 25 and 65 years of age, and that in this all-important interval rural males and both urban and rural females possess death-rates lying nearly at the same level, while urban males on the average throughout the whole of England *die at double this rate or over*, then it becomes manifest that the sanitarian stands face to face with a great problem worthy of the completest investigation.

When it is remembered that the vast majority of the males of the country are engaged upon urban occupations, it is easily realised that this doubled death-rate from phthisis means an annual loss of several thousand males in the economically most efficient period of life. From this the purely materialistic standpoint alone, each such life is worth some hundreds of pounds to the community, so that the aggregate annual loss from deaths alone far exceeds what it would cost to limit the loss on the lines presently to be proposed. The death-loss alone is, unfortunately, not the only toll, for millions of pounds annually are lost by the incapacity for work of those suffering from the disease. In the next place, these sufferers are a constant source of danger as carriers of disease to those who work or live with them, and if the great excess of phthisis amongst these urban males could be cut off by tackling its causes at their sources, there would doubtless occur a decrease in the incidence of phthisis amongst all the rest of the community.

Lastly, this enhanced rate amongst employed urban males, which is responsible for the death of about one urban male in every five dying between 25 and 65, is one of the causes of disparity in numbers between males and females in the physiologically reproductive period of life. This disparity was sufficiently marked before the war and is now being accentuated by the large loss in young adult male life, so that any influence which can be set to work to reduce the male death-rate from phthisis towards that obtaining amongst females is also highly desirable on sociological grounds.

Causes of the Disparity in Incidence.

Before proceeding to discuss the remedial measures which ought to be set in action, some additional discussion of the causes of the disparity is essential, since these measures themselves must be based upon the true causation of the phenomenon.

In the first place, the enormous difference during the working period of life between urban and rural males is not due to housing conditions, for if this were so similar differences ought to be seen between urban and rural females, but, as the graph shows, no such characteristic difference exists. The form of the curve varies somewhat as between rural and urban females, the maximum death-rate falling somewhat later amongst the town's women, but taken throughout the whole period of life the death-rates are almost identical in value.

Again, if the predisposing factor to the high prevalence amongst urban males were some factor of urban environment not connected with employment this ought to be obvious in the earlier years of life, but up to the twentieth year of life the four curves run fairly close together on nearly parallel courses. In fact, so far as differences exist, males, both urban and rural, are healthier than females, and in the case of both sexes urban dwellers are healthier than rural dwellers. It is quite clear that the difference is not one due to sex, occurring after the twentieth year, for in that case the rural males ought to be up somewhere alongside the urban males, instead of where they actually stand nearly at the levels of both urban and rural females.

The problem under consideration is, then, one which appears in five to ten years after the commencement of employment and persists throughout the working period of life, attaining its maximum between the thirtieth and sixtieth years. It is characteristic of male urban workers, and is inconspicuous amongst urban females, who do not continue to work in factories and large workshops in large numbers after the thirtieth or thirty-fifth year, or at least did not do so in pre-war times, to which these statistics refer.

It might be urged that if the effect is due to urban working conditions it ought to start at the commencement of employment—that is to say, about the fifteenth year. The reply to this is that these records are records of deaths due to a chronic disease, and that some years are required to produce debility and infection and for the disease to run its course to a fatal issue. There are certain occupations in which there is no question of the conditions of labour conducing to phthisis, such as printers, bootmakers, quartz workers, cutlers, grinders, and file-makers. In all these trades there is a latent period of variable length but always of some years' duration, and the form of the curve of mortality from phthisis in such trades conforms in general to that shown in Diagram 1 for all urban males.

It would appear from these considerations clear almost to a demonstration that the greatly enhanced prevalence of phthisis amongst urban male workers is not due to housing conditions, faulty though these may be, for the females, who stay more at home than the males, are not subject to the effects, nor are the males until a few years after they have passed to their occupations. The most obvious cause revealed by a statistical study is accordingly some circumstance, or set of circumstances, connected with the daily occupation.

Observations within the factory of the conditions of work, of the correlated variations in different trades, and a study of the illnesses shown by the Health Insurance cards have convinced me that this is the true cause at work.

The Two Main Factors.

It may be said at once that the two main factors are long-continued strain at work under unhealthy conditions and infection of men so reduced in resisting power by fellow-workmen actually at work alongside them while suffering from open phthisis and disseminating the bacillus of the disease. This is proven by the fact that the heaviest incidences of the disease are found amongst those occupations in which the demand for muscular exertion is so slight that a consumptive worker can still continue at work intermittently until he is in the last stages of the disease and in a highly infectious condition. If such an occupation is carried on in a workshop where the atmospheric conditions are bad, and long and irregular shifts of work, including a good deal of night work, are frequent, and if the workers come into close contact, then the death-rate from phthisis becomes a maximum one. Sedentary occupation alone, even accompanied by long hours of labour, does not lead to an excessive death-rate provided there is sufficient isolation and lack of means of infection. Again, the workers may be crowded together indoors, but if the exertion be sufficiently strenuous to preclude the sufferer from phthisis continuing at work there is not a high occupational death-rate from the disease.

But if the working conditions are such as to favour infection from man to man, and superadded to this there be a close stagnant atmosphere, long hours of labour and much overtime unevenly distributed, eating of meals in common on the premises under unhygienic conditions—in short, all those conditions which reduce stamina and induce mental and physical depression—then a maximum death-rate from phthisis appears.

These conclusions are the result of observations in the workshops of occupations heavily hit by phthisis, and are confirmed by the opinions of employers and employees in such trades. In so far as improvements in the deleterious conditions mentioned have occurred in trades over a considerable period of years, the statistics of the trades unions demonstrate that there have taken place corresponding improvements in the amount of illness and deaths from phthisis. Space will not permit the marshalling of all the evidence which goes to establish the truth of this position, but a few facts may be quoted in illustration from my observations in the different branches of the printing trade.

Investigations in the Printing Trade.

Examination of the obituary lists of the membership of the two large unions of compositors over a period including the 35 years previous to the outbreak of war proves that the relative death-rate from phthisis fell during that interval from one death from phthisis in three total deaths to less than one death from phthisis amongst five total deaths. This improvement far exceeds that seen in the average of all urban males in the same period, and must be ascribed to the better printing shops which now exist, the larger use of printing machinery, and the more regular hours worked. It is thus due to two primary factors: less strain on the workman and less chance of infection.

It is commonly supposed that compositors are the most heavily hit in the printing trades by phthisis. This is not, however, the case, for amongst one unfortunate set of these workers—viz., the operative printers' assistants, *nearly one-half of all the deaths are due to phthisis even in present times.* A close investigation soon discovers the cause of this appalling death-rate. In addition to all the disabilities in the nature of the occupation which cause the high death-rates amongst the members of the other printing fraternities these operative printers' assistants often work long periods of overtime at night. There is a pernicious habit, largely obtaining in this branch, of working an all-night shift in order to turn out weekly papers. This long shift is paid for well as overtime, and the men are so induced to perform it, to the great detriment of their own health. A man taking such a long shift undergoes the following strain. After a full day's work he continues on at work all night, and then goes on again for a full day's work the following day, so completing a continuous working period, save for short meal periods within the works, of 30 hours. Another set of workers, better paid and organised, called machine managers, do not commit this error, but relieve each other after shifts of normal length, and their death-rate from phthisis is only about one-third of that of the operative printers' assistants.

The clearest evidence has been obtained by tracing out many instances that both compositors and printers' assistants ill with phthisis and discharging bacillus-laden sputum go on working intermittently in the printing shops to within a few days of their death.

There were numerous cases discovered of men off work for several weeks with the cause of illness certified as catarrh, and in certain cases these died later after having been at work intermediately, with the cause of death certified as phthisis. Men showing all the facies of phthisis have been observed at work during visits to the workshops in most intimate proximity to other workmen.

In many establishments in the hand-composing section, to save a little space the composing frames containing the type are set back-to-back, so that a consumptive printer can spray the man working opposite to him and facing him at a distance of only 2 or 3 feet. If the latter individual is predisposed to infection from the nature of his work and general environment, it is easy to see how the infection can be passed on.

Instances might be multiplied from this and other trades which would go far to explain why there is such an abnormally high death-rate from phthisis amongst urban males, but, admitting the conducive elements, let us proceed to consider remedies.

The Need of a Medical Service in Factories.

Practical experience in the tackling and successful reduction almost to vanishing point of another type of illness amongst munition workers, which had cost a good many lives and caused much sickness and economic loss of time and efficiency, has convinced me that the urgent necessity is the institution of an efficient factory service of medical men. The doctor must be introduced into the factories and work-

shops to do battle with this evil; he cannot achieve victory by waiting in his consulting room till the patient comes to him of his own initiative. The patient himself is often one of the last to realise that he is seriously ill, and even then has always the *spes phthisica* to buoy him up that he is getting better. The foreman, or shop steward, and his fellow-workmen know much better than himself that he is running down and slowly growing weaker, but all under present conditions are unable to extend aid to him, and so he goes on intermittently working and exposing others to danger.

It is a melancholy picture over which industrial hygiene wrings its hands in vain, while men go on dying who ought to be saved. Yet the problem is not one of colossal dimensions if only statesmen and doctors could be persuaded to tackle it together and mutually assist in its solution.

Even in one of the occupations most heavily scourged by phthisis, such as the printing trades, there is not at any given time more than about one man in between 200 and 300 employed actually ill with phthisis. If these could be efficiently treated and prevented from infecting others, and at the same time general conditions altered in a manner which would involve but little expense, an enormous improvement could be effected.

A national colony containing hygienic dwellings and thoroughly sanitary workshops, which might serve as models for all the rest of the country, could be constructed in which these affected workmen could work at their own occupations, as has already been suggested by Dr. J. E. Esslemont, of Bournemouth. Here as recovery progressed the patient, instead of being suddenly thrust back into the full strain of work under conditions which make for the re-establishment of the disease, could be brought back to full vigour by a graduated course of resumption of his own work, and far fewer relapses would occur. On return to the ordinary workshop he would for a time remain under careful supervision by the doctor of the Industrial Medical Service who had medical supervision of the workshop.

Although such a colony would repay the nation many times over the cost of its establishment, in the present only half-awakened state of the public conscience over health protection it might be considered by statesmen Utopian, or unrealisable on account of opposition of employers and employees.

A fairly considerable amount of acquaintance, and many friendly discussions, with both employers and secretaries of trades unions and foremen of shops, have convinced me that there would be no opposition, but rather the most friendly coöperation, over any practical scheme to improve the health and physique of the workers. All that is required is tact and friendliness and education as to the nature of the scheme and the result aimed at, and then works managers, foremen, and workers become as enthusiastic as the doctor.

Personally, I have always found in research in factories employers willing to spend money in equipment and for experimentation, and workers in most cases willing to undergo considerable inconvenience in experimentation to benefit themselves and their fellow-workers.

Functions of the Proposed Industrial Health Medical Service.

It would be by no means necessary in such an Industrial Health Service for the doctor to make medical examinations of all workers at frequent intervals, as is done, for example, in working the School Medical Service. Such a procedure would arouse opposition, would require an inordinately large medical staff, and would not repay the labour spent upon it. It has always been to me an open question whether too much of the time of the school medical officer is not tediously and monotonously spent in this fashion, and whether more practical results would not be attained by enlisting the services of the teachers and giving the main attention to children who may need aid themselves or be a source of danger to their school-mates.

At any rate, it is from the preventive point of view that I would earnestly urge the formation of an Industrial Health Medical Service, and upon the lines on which I should project it I have estimated that it could be efficiently manned for England and Wales with a staff of about 1500 medical men. This new corps would in no wise interfere with the work of the private practitioner or panel practitioner; its function would be to see, by inspection of factories and by education of those in charge of them, that sanitary conditions in factories were improved, and when resistance or wilful obstruction could not be overcome by other means, then by compulsion securing amendment. Much could be achieved here by a pooled system to raise compensation payment to workpeople turned off for being in enfeebled health or a source of danger to the health of others. It could be made to pay the factory employer to keep his workshops sanitary and his people healthy.

After this survey of material environment the next concern of the factory doctor would be the health of the workers individually, with especial stress upon the preventive side and upon those conditions which precede chronic illnesses. For example, the prospective consumptive patient should, if possible, be caught before he is consumptive; a week or two of rest at the needful moment, when as yet the worker would have had no dreams of going to a doctor, may save many months in a sanatorium later.

Utopian, it may be said—Who will pay the worker his wages while he goes off to take a fortnight's holiday? On the contrary, I claim it will repay both the nation and the employer, the worker and the trades unions' funds, over and over again. The worker is not to be allowed to propose holidays for himself; an entirely unbiased doctor is going to prescribe it on obvious physical signs which no malingerer can induce.

Rarely have I gone into a large workshop containing 200 or 300 workers that I have not observed one or two who ought to have been resting. The neglect of such incipient cases of illness is a foolish, short-sighted policy for all concerned.

The Relations of the Scheme to the General Practitioner.

It has been said above that this new service would be no rival or competitor to the private or panel practitioner; on the contrary, it would be a succour and a support to him. The competitors for private work would be so much the fewer by the number of men willingly drafted into the industrial health service, but none of the insured workers, who are all panel patients, would be withdrawn from the panels. The panel patient with a chronic and oft-recurring illness requiring periods off work under medical treatment is a good asset at present to no one, and least of all to the panel doctor. In fact, it is unfair both to doctors and patients that such chronic illnesses as phthisis should be treated under a panel system of capitation payment. It is an undue risk to ask the doctor to take from the financial point of view, but it is a still graver risk for the patient, since it often involves the loss of his life. How can a panel doctor treat a case of phthisis in a working-class dwelling when the patient, and probably his dependants also, have only an allowance of a few shillings a week to live on and the patient keeps on intermittently going on and off work? It is certainly better than when the patient had no weekly allowance and had to pay his doctor's bill, but even yet it is a disgrace to civilisation and a real live danger to the community and ought to be abolished as soon as possible.

It is such cases that the medical officers of the new corps would seek out early in the workshops and send to suitable sanatoriums attached to the Industrial Health Service. This is not going to cost industry and the country more; it is going to cost less, very much less, than practically unrestrained phthisis is costing, and many thousands of healthy valuable lives will be saved, and countless families spared the greatest sacrifice, followed by grinding poverty.

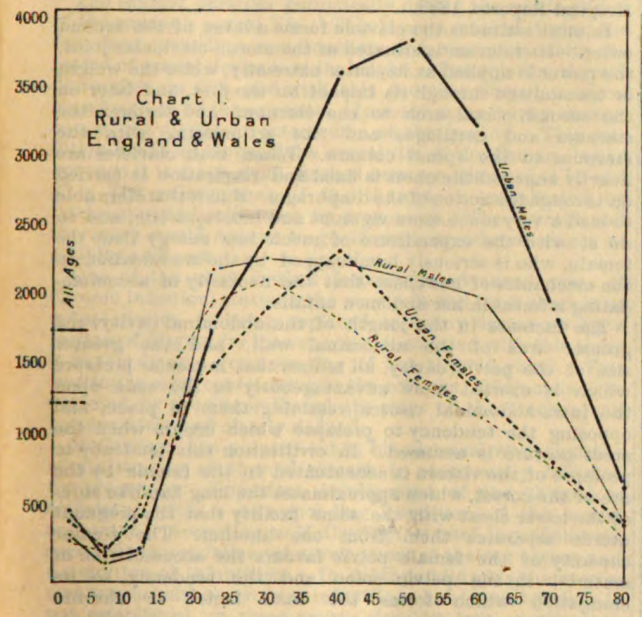
There never was a more opportune moment than is the present for initiating this great reform. Practically all the young medical men that the medical schools have turned out in the past ten years, who are still living, are in khaki carrying on superbly one of the noblest services that medical science has ever rendered to humanity. The majority of them during the past four years have learnt the régime of corps work, preventive work, and hospital treatment, scarcely a man in this young virile force has a practice worth coming home to, and they deserve better of their country than being turned into medical squatters.

Moreover, as this paper shows, the medical needs of the homeland are crying out for good team-work on the side of preventive medicine, applied not merely to material environment, but to suffering men and women. Many of these young men have been training for just this work that is crying aloud to be undertaken, and most of them probably possess little of either zest or training for private practice.

All that is needed is a statesman of power and imagination who will put this scheme in being, and so let Great Britain lead the world to the greatest conquest that has ever been won.

Charts to Illustrate the Difference in the Prevalence of Pulmonary Phthisis between Rural and Urban Conditions.

In all the charts continuous lines show male death-rates and interrupted lines female death-rates per million at the ages shown on the base line. The thicker lines represent urban and the thinner lines rural areas. The horizontal lines at the left of each chart show average death-rates at all ages.



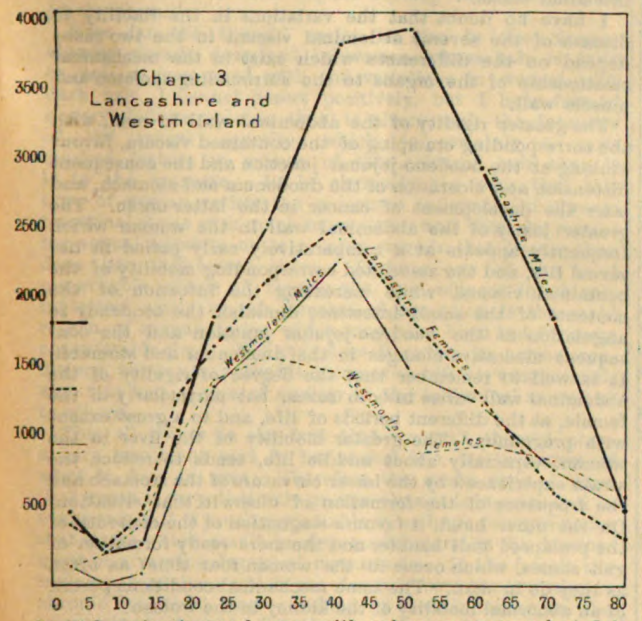


Chart 1 contrasts rural areas with urban areas, as selected by the Registrar-General. The urban areas were Glamorgan, Lancashire, London, Middlesex, Monmouth, Northumberland, Nottingham, Stafford, Warwickshire, Yorkshire (East and West Ridings), with a population of 16,465,427. The rural areas were Buckingham, Cambridge, Cornwall, Hereford, Huntingdon, Lincoln, North Wales, Norfolk, Oxford, Rutland, Salop, Somerset, South Wales (less Glamorgan), Suffolk, Westmorland, Wilts, with a population of 4,265,578. It is obvious that a purer contrast could easily be made with a heightened effect, but still the difference is most striking.

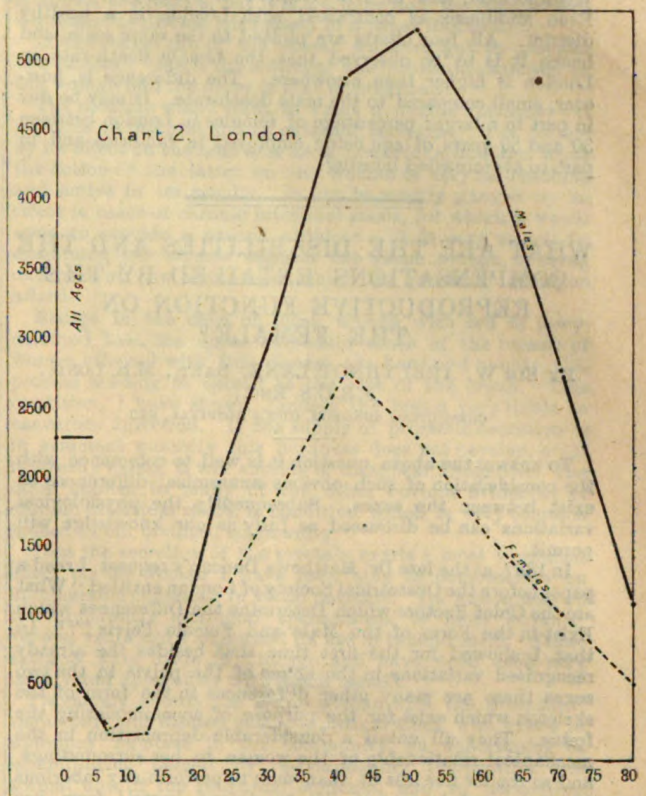
Chart 2 shows the London area, which for clearness is left uncontrasted with other areas to bring into as strong relief as possible the enormous difference between males and females. Whether the cause be that ascribed in this paper or not, here is a matter of national importance.

Chart 3 contrasts Lancashire and Westmorland, the two heavier curves showing Lancashire and the two lighter ones Westmorland. Observe how all four curves run together until about the twentieth year, and then how Lancashire males alone soar in death-rate away from the others.



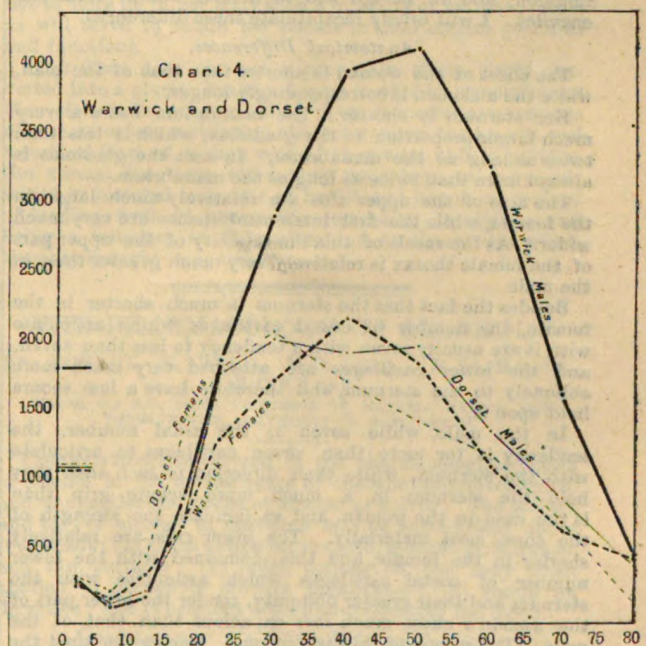


Chart 4 shows the same for Warwickshire and Dorset, and exactly the same holds for the West Riding and North Riding of Yorkshire. It is, in fact, a universal rule that in typical rural districts death-rates of males and females lie close together, whilst in urban districts the male death-rate is double that of the female or higher.

The four charts given are selected to illustrate differences between rural and urban conditions. Many others could be given, and the statistics of the whole country prove the enormous effects of

urban conditions of labour upon male deaths from phthisis. The differences are in no sense geographical, for rural areas in Lancashire can be picked out which are as healthy as Westmorland, and in Warwickshire as healthy as Dorset. Even Middlesex as contrasted with London is a healthy district. All four charts are plotted to the same scale, and hence it is to be observed that the female death-rate in London is higher than elsewhere. The difference is, however, small compared to the male death-rate. It may be due in part to a larger percentage of females in London between 30 and 50 years of age being employed in factories and in part to overcrowded housing.

WHAT ARE THE DISABILITIES AND THE COMPENSATIONS ENTAILED BY THE REPRODUCTIVE FUNCTION ON THE FEMALE?

BY SIR W. ARBUTHNOT LANE, BART., M.S. LOND., F.R.C.S. ENG.,
CONSULTING SURGEON, GUY'S HOSPITAL, ETC.

To answer the above question it is well to commence with the consideration of such obvious anatomical differences as exist between the sexes. Subsequently the physiological variations can be discussed as fully as our knowledge will permit.

In 1887, at the late Dr. Matthews Duncan's request, I read a paper before the Obstetrical Society of London entitled "What are the Chief Factors which Determine the Differences which Exist in the Form of the Male and Female Pelvis?"[1] In that I showed for the first time that besides the already recognised variations in the shape of the pelvis in the two sexes there are many other differences in the form of the skeleton which exist for the purpose of accommodating the fœtus. They all entail a considerable depreciation in the mechanical relationship of the woman to her surroundings, and so render her less fit than man to perform any laborious function, and in savage life to defend herself from her enemies. I will briefly recapitulate these differences.

Anatomical Differences.

The chest of the woman is shorter than that of the man, while the abdomen is correspondingly longer.

Her sternum is shorter. The manubrium bears a very much larger proportion to the gladiolus, which is less than twice as long as the manubrium. In man the gladiolus is always more than twice as long as the manubrium.

The arcs of the upper ribs are relatively much larger in the female, while the first intercostal spaces are very much wider. As the result of this the capacity of the upper part of the female thorax is relatively very much greater than in the male.

Besides the fact that the sternum is much shorter in the female, the number of costal cartilages which articulate with it are usually seven with a tendency to less than seven, and the lower cartilages are attached very much more obliquely to the sternum, and therefore have a less secure hold upon it.

In the male, while seven is the usual number, the tendency is for more than seven cartilages to articulate with the sternum, while their direction is such that they hold the sternum in a much more secure grip than is the case in the woman, and so increase the strength of the chest most materially. The lower ribs are relatively shorter in the female, and this, combined with the fewer number of costal cartilages which articulate with the sternum and their greater obliquity, render the lower part of the woman's chest much less capacious than that of the male. The reason of this is obvious. During the time the abdomen is occupied by the fœtus in the later months of pregnancy the respiratory capacity of the lower segment of the chest is considerably reduced, so that a correspondingly greater change must be carried on in the lungs in the relatively more capacious upper thorax. This explains the mode of respiration which is peculiar to the sex. The arrangement of the lower chest also permits of its lateral expansion by the pregnant uterus.

[1] Trans. Obstet. Soc., 1887.

The male and female types of thorax are exaggerated in the case of cervical and bicipital ribs. These conditions are very well illustrated in a paper entitled "Cervical and Bicipital Ribs in Man," which I published in the Guy's Hospital Reports, 1883.

In most attitudes the clavicle forms a lever of the second order. Its fulcrum is situated at the sterno-clavicular joint, the power is applied at its outer extremity, while the weight is transmitted through its impact on the first, and later on the second, costal arch to the sternum, and through the sternum and cartilages and ribs articulating with the sternum to the spinal column. When both clavicles are heavily engaged the chest is fixed and respiration is carried on through the action of the diaphragm. Man is therefore able to lead a very much more vigorous and laborious life, and to do so with the expenditure of much less energy than the female, who is seriously handicapped by the modification in the mechanics of her chest that the necessity of accommodating a fœtus in her abdomen entails.

The increase in the length of the abdominal cavity, the greater area of the abdominal wall, and the greater size of the pelvic cavity, all reduce that muscular pressure which is exerted more advantageously in the male upon the intra-abdominal viscera, retaining them in place, and opposing the tendency to prolapse which occurs when the erect posture is assumed. In civilisation this tendency to prolapse of the viscera is accentuated in the female by the use of the corset, which approximates the long flap-like sides of the lower chest with the same facility that the pregnant uterus separates them from one another. The greater capacity of the female pelvis favours the accumulation of material in the pelvic colon and the tendency to its elongation which forms the basic factor in chronic intestinal stasis.

I have no doubt that the variations in the liability to disease of the several abdominal viscera in the two sexes depend on the differences which exist in the mechanical relationship of the organs to the surrounding skeleton and muscle wall.

The greater rigidity of the abdominal wall in man, with the corresponding cramping of the contained viscera, favour kinking at the duodeno-jejunal junction and the consequent distension and ulceration of the duodenum and stomach, and later the development of cancer in the latter organ. The greater laxity of the abdominal wall in the woman which frequently appears at a comparatively early period in her sexual life, and the associated corresponding mobility of the contained viscera, while increasing the infection of the contents of the small intestine, diminish the tendency to angulation at the duodeno-jejunal junction and the consequent ulcerative changes in the duodenum and stomach. It is well to remember that the degree of rigidity of the abdominal wall varies in both sexes, but particularly in the female, at the different periods of life, and to a great extent with pregnancy. The greater mobility of the liver in the woman, especially about middle life, tends to reduce the strain experienced by the lesser curvature of the stomach and the frequency of the formation of ulcers in that situation. On the other hand, it favours stagnation of the contents of the prolapsed gall bladder and the more ready formation of gall stones, which occur in the woman four times as often as they do in man. The same mechanical conditions permit of an abnormal mobility of the kidney in the woman.

The following proportions which I have obtained from the statistics of the Mayo Clinic are very suggestive. 75 per cent. of peptic ulcers are duodenal; 11 per cent. of patients with gastric ulcer have duodenal ulcer; 3·2 per cent of cases of duodenal ulcer have gastric ulcer; more than 30 per cent of all cancers in man are in the stomach; cancer of the stomach occurs in the proportion of 38 per cent. in the male to 22 per cent. in the female; 85 per cent. of all cancers and ulcers in the stomach involve the lesser curvature; diverticulitis occurs in the proportion of 66 per cent. in the male to 33·4 per cent. in the female; and cancer of the rectum is a little more common in the male. With a view of demonstrating the mechanical factor more clearly I have attempted to obtain further details as to the incidence of disease at different ages in the two sexes, but without success.

The Part Played by the Thyroid Gland.

As regards the various organs of the body, that one which is most closely associated with the sexual function in the female is the thyroid gland. The variations in the size of the

thyroid afford clear confirmation of the preponderating influence of sex in the woman as compared to the part it plays in man.

The thyroid enlarges periodically during the whole period of the woman's sexual life. This is more marked during the few days preceding menstruation, and continues while the period of sexual desire is at its height. After this the thyroid diminishes in size, and with this decrease there is a corresponding loss of the appetite. In some cases it may amount to a strong dislike for intercourse at this period. This condition exists all through the sexual life of the woman, but in our race it is much more marked between the ages of 19 and 23. The enlargement of the thyroid is accentuated by intercourse and still more by pregnancy. The thyroid and the ovary would appear to go through associated stages of activity and rest.

One of the most marked features in advanced cases of chronic intestinal stasis in the woman is the total absence of sexual desire, it being replaced in many instances by a feeling of disgust for intercourse. Associated with this there is in this disease great wasting of the thyroid gland. This wasting is most conspicuous in the isthmus, which cannot be detected by the finger though the rings of the trachea can be accurately and clearly defined.

McCarrison has pointed out in his classical work that the administration of thyroid extract is occasionally followed by pregnancy. Imperfect development of the thyroid is associated with a corresponding condition of the sexual apparatus. According to McCarrison, "total loss of thyroid secretion causes failure of development of the sex organs and a condition of infantilism. In subthyroidic girls the ovaries and uterus either remain infantile when menstruation is not established, or these organs develop late, resulting in amenorrhœa."

How far the thyroid varies in size in the circumstances already described in women whose hair is towy or red, as compared with the variations in women with dark hair, I cannot assert positively, but I have formed a very definite opinion that it alters with the intensity of the sexual appetite, which is certainly a more marked feature in women of this coloured hair than it is in the brunette. It is obviously the case that this type of woman resists the poisonous influences of chronic intestinal stasis with much more vigour and that she retains her sexual appetite up to a later stage in that disease than does her dark-haired sister. Perhaps one of the most remarkable effects of freeing the ileal effluent in chronic intestinal stasis by the removal of the colon is the rapid return of sexual desire, which may have been lost for some considerable time. Not only does it return to normal conditions, but in many cases it becomes manifestly exaggerated, and may be a source of anxiety to the individual as well as to others.

This all points to the fact that woman's thyroid plays a very important part in her sexual life, far in excess of what it does in man. Therefore the strain exerted upon that organ is very distinctly greater than it is in man, and in consequence it is much more liable to undergo changes under that stress which result in degeneration and in the development of a varying degree of myxœdema. In the female the toxins or organisms which are derived from the intestine in chronic intestinal stasis produce by their influence on the overstrained thyroid, directly through its blood-supply or indirectly through its nerve-supply, a far greater change than in man, and this occurs during the period of greatest sexual activity. The incidence of exophthalmic goitre in the two sexes affords a very good illustration of the truth of this view. 30 per cent. of the cases occur in women between the ages of 20 and 25. Murray found that it arose 18 times more often in females than in males, while Mackenzie estimates the proportion as 9 to 1. Personally I would make the proportion very much higher than either of these observers, as I believe that a number of trivial cases escape observation and recognition.

McCarrison has shown that up to the age of puberty the sexes are affected by endemic goitre almost equally. From the age of puberty onwards females are much more liable to suffer than males. He finds what he calls the simple toxæmic goitre as we see it in this country to be incomparably more common in the female than in the male. He also insists on the serious damage which the infant sustains from the presence of any form of toxic goitre in the mother.

Two Factors in the Sexual Life of Woman.

I have here dealt with the function of the prostatic fluid as it affects the female, but it is too large and too complicated a question to discuss adequately in a paper like this.

In the sexual life of the woman we have got to consider two factors. One is the action of the prostatic secretion on the woman and the other is that of pregnancy.

The prostate would seem to exert a double function. It provides an internal and an external secretion. The former by its effect on the man acts as a powerful stimulant, while the action of the latter on the woman is very far-reaching and active in its results. It can be readily gauged by its effect in cases of chronic intestinal stasis, for which it would seem to provide a natural antidote. It is easy to tell by examining her breasts whether the static woman is being deprived of the advantages which the prostatic secretion affords.

Except in the case of those women with red or towy-coloured hair, the upper and outer zones of the breasts of women affected with this disease are hard and nobbly, this process tending to spread to the rest of the organ. This condition, I have shown, renders the breast very liable to cancerous infection. If the supply of prostatic secretion is in sufficient quantity this hardness does not develop, or, if it already exists, it will subside or disappear altogether. The same applies to many of the other obvious evidences of chronic intestinal stasis, a condition which is very common indeed in our civilised community.

That the secretion of the prostate exerts a most beneficial effect on the woman I have been able to demonstrate on innumerable occasions in static patients. Its action also on the apparently moribund spermatozoa is most striking. Several years ago I suggested its use in tabloid form. These extracts were made in Chicago and have been used very largely and apparently with much benefit.

Pregnancy affords the static woman with the prolapsed, angulated, and dilated gastro-intestinal tract, who exists in enormous numbers in the community, an opportunity of rehabilitating herself by re-establishing temporarily the normal flow of the intestinal contents, and so permitting her to store up in her body such a quantity of fat and muscle as will serve to retain her viscera in their correct positions and functions.

How often does one see a poor thin static virgin converted into a plump, healthy, happy mother by a pregnancy? How often is the surgeon called upon to perform operations of a more or less mutilating character upon the breasts and intestinal tract of women who, if they were able to perform the normal functions which they were born to carry out, would be restored to a state of health and happiness instead of leading lives of necessarily increasing invalidism and being a nuisance to themselves and to those with whom they are brought in contact?

THE PHARMACOLOGY OF ALCOHOL.*

BY ROBERT B. WILD, M.D. LOND., M.SC. MANCH., F.R.C.P. LOND.,
MAJOR, R.A.M.C. (T.F.); PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, UNIVERSITY OF MANCHESTER.

I INTEND to confine myself to the pharmacological action of alcohol in the narrow sense of the word pharmacological and to consider the action of alcohol as a drug. The actions and uses of alcohol in medicine may be summarised under four heads: (1) Local action on the skin, mucous membranes, and raw surfaces; (2) reflex actions on the body when applied to accessible mucous membranes; (3) action on digestion; and (4) actions after absorption into the blood.

Local Action of Alcohol on External Surfaces.

Its action on the external surface depends upon its volatility, its affinity for water, its power of coagulating proteid, and its antiseptic action.

Owing to its volatility it is an almost invariable ingredient of cooling lotions when allowed to evaporate freely from inflamed surfaces. Somewhat paradoxically the same property determines its inclusion in most liniments and other preparations intended to irritate the skin, for when the alcohol

* Part of a paper read before the Society for the Study of Inebriety on Oct. 8th, 1918.

is not allowed to evaporate the vapour easily penetrates the skin and irritates the sensitive and highly vascular tissues beneath the horny epidermis. Its affinity for water causes it to harden the tissues by extracting water from them, and this hardening effect is increased by the coagulation of the proteid in the still unkeratosed or partially keratosed cells of the deeper layers of the epidermis. In a more dilute form the same properties are used in astringent gargles and lotions.

The antiseptic properties of alcohol are responsible for the existence of a great part of our museums of natural history, anatomy, and pathology, and although inferior in degree to many other antiseptics they add largely to its value as a local application. The fact seems too little known that the most powerful antiseptic effects are produced, not by absolute alcohol, but by alcohol of from 40 to 70 per cent.[1]

Reflex Actions of Alcohol.

The reflex actions which follow the local application of alcoholic solutions of a strength of 20 to 25 per cent. or over to the mucous membrane of the lips, mouth, and pharynx are of considerable importance because it is largely to these actions that alcohol owes its popular reputation as a stimulant. Its action is that of a local irritant and on a par with the action of ammonia or strong acetic acid and many other volatile irritants. The effects observed are a rousing of the latent consciousness, an increase in the movements of respiration, an increase in the force and frequency of the heart—in short, a hastening of the recovery.

That these results are reflex is shown by the fact that they begin at once, long before any of the alcohol can have been absorbed; that they occur even when none of the drug is swallowed but merely retained for a short time in the mouth and then rejected; that they are proportional to the strength of the alcohol and not to the quantity, a few drops of strong alcohol merely applied to the lips is often effective, while a considerable quantity of dilute alcohol produces little effect, even if swallowed; finally, they do not occur if alcohol is injected directly into the circulation in animals.[2]

The effects are also of a very temporary character and pass off in about ten minutes unless the alcohol is swallowed, when they may persist for half an hour, probably owing to the additional reflex from the mucous membrane of the stomach. I think much confusion has been caused in the discussions upon the action of alcohol by the failure to distinguish sharply between these reflex effects common to all volatile irritants and the effects of alcohol after absorption.

The Action of Alcohol on Digestion.

The action of alcohol on digestion is made up of two factors—viz., its action on the stomach and its action upon the stomach contents. The former is a combination of its local action on the walls of the stomach with the effects of its reflex action; the latter is purely chemical and due to the action of the drug upon the gastric secretions and upon the constituents of the food.

It appears to be established that in dilutions up to 5 per cent. no deleterious effects are produced upon the action of the digestive ferments, nor any hardening of the proteid food which would make it more slowly digested. In this dilution the activity of gastric digestion is increased (1) by the action of the alcohol upon the mucous membrane of the mouth and pharynx, causing a reflex flow of saliva and gastric juice; and (2) by its local action upon the mucous membrane of the stomach, causing increased vascularity and a further flow of gastric juice.

The stomach is practically a closed cavity with a temperature of 98·6° F., and no matter how dilute a solution of alcohol may be, the alcohol will be partially vapourised at this temperature, and that part of the stomach unoccupied by food will contain a comparatively concentrated alcoholic vapour which is a marked irritant to a delicate mucous membrane. I believe this is the cause of the feeling of warmth in the stomach which usually follows the taking of even small quantities of alcohol, and that it is the vapour rather than the alcohol in solution which acts as an irritant and causes the increased vascularity. The rapid absorption of alcohol from the stomach—as compared, for example, with water—is probably also due, in part, at any rate, to the alcoholic vapour diffusing rapidly through the delicate epithelial cells of the mucous membrane.

In concentrations over 5 per cent. almost all observers are agreed that alcohol delays digestion by interfering with the action of the digestive ferments and possibly hardening the proteids of the food, while strong concentrations set up an actual catarrhal inflammation of the stomach, as was demonstrated many years ago by Dr. Beaumont in the classical case of Alexis St. Martin.

The increased movements of the stomach supposed to be set up by alcohol and so aid digestion have not been demonstrated by the more recent experiments, and it is doubtful if they occur in the case of dilute solutions. In certain concentrations, however, alcohol acts like a volatile oil, regulates peristalsis, relieves spasmodic pain, and removes flatulence.

Action of Alcohol after Absorption.

It is now universally admitted that the main action of alcohol after absorption is on the central nervous system, and I think it is also admitted that the action of large doses is always a depressing or paralysing action. The various centres are affected in the inverse order of their development so that the first to go are the highest centres of judgment and emotional control, comparison, and inhibition. Those inhibitory centres which are so constantly in action in all civilised communities to restrain the inclinations and impulses of the natural man are early affected, and as civilisation becomes more complex and life more intricate, these inhibitory centres are sometimes strained to breaking point. In such cases alcohol may benefit a patient by giving his inhibitory centres a rest and time for recuperation. Released from the habitual control of the higher centres the lower centres tend to become more purely reflex and to over-act in response to various stimuli, giving rise to that increased activity, muscular or emotional, which, together with the reflex effects already considered, is responsible for the popular conception of alcohol as a stimulant. As the action of the alcohol proceeds these lower centres are themselves paralysed and the paralysis spreads to the still lower motor centres, then consciousness itself is lost and the full action of alcohol as a narcotic poison is manifested.

The question is, however, more difficult in the case of the small doses of alcohol usually given for therapeutic purposes. The study of the various published researches leads me to the conclusion that so far the case for any preliminary stimulant action of alcohol on the central nervous system is not proven, and that all the phenomena attributed to such action can be equally well explained by assuming the action of alcohol to be consistently depressing throughout.

I cannot now go into the subject of the anatomical basis for the action of alcohol upon the brain cells—whether it is directly upon the cell protoplasm itself, or in combination with the lipoids of the brain cells, or upon the dendrites so as to interrupt communication of impulses from neuron to neuron; any or all of these hypotheses are possible. It appears, however, to be certain that the neurons of centres having certain functions are more sensitive than others, and probably the relative sensitiveness of the centres may vary somewhat in different individuals. With small doses, not sufficient to cause noticeable excitement, painful sensations are less acute and sources of mental worry, anxiety or irritation no longer occupy so large a place in the field of consciousness; there is consequently a feeling of euphoria or general well-being, and a tendency to drowsiness or actual sleep if the environment is favourable. It is this sedative influence which is often so valuable in dangerous and exhausting illness, and the judicious use of alcohol may suffice to turn the balance in a debilitated and despairing patient. I wish to lay stress on the fact that this effect is obtained by small doses, and is not preceded by any indication of a preliminary stimulation unless the drug is given in sufficient concentration to cause a temporary reflex effect.

Effect on Heart and Blood-Vessels.

The action of alcohol on the circulation after its absorption into the blood has been carefully worked out by experiments upon animals. The results are not entirely in accord, but the conclusion we are forced to come to is that there is no proof from these experiments that alcohol present in the blood in any concentration compatible with the amount given and with the symptoms exhibited has any action on the heart or blood pressure sufficiently marked to be of importance in therapeutics. The presence of alcohol in the blood to an extent of 0·1 per cent. causes definite symptoms of intoxication, and when given in therapeutic doses where such symptoms are never produced the quantity in the blood must be less than this amount.

While evidence of stimulation is absent, one result of perfusion experiments upon the isolated heart by Loeb,[3] Dixon,[4] and Hamill[5] is worthy of notice—viz., that in an exhausted or feebly-beating heart the addition of small quantities of alcohol to the perfusing fluid causes an improvement in the beat, and at the same time some of the alcohol was removed from the perfusing fluid, having apparently been utilised by the heart muscle as a source of nourishment. The improvement in the circulation clinically observed in cases of exhausting disease is probably due to a similar action, combined with a sedative action on the nerve centres which regulate the action of the heart, and also to a diminution of pain and anxiety.

The effect upon the pulse-rate in healthy men appears to vary with the individual, and when the disturbing influences of movements and excitement are avoided, as in the experiments of Higgins,[6] an increase of 1 to 4 beats per minute was found in 45 per cent. of the experiments, and in 55 per cent. no acceleration occurred.

The most marked effect of alcohol upon the blood-vessels is seen in the skin. The flushing is due to a paralysis of the muscular fibres in the walls of the small vessels which results in the capillaries being distended with blood; when frequently repeated a permanent enlargement of these vessels ensues. The increased amount of blood in the skin may relieve a possibly dangerous congestion in certain cases, and also promotes perspiration. Most important, however, is the effect of this dilatation of the superficial vessels upon the temperature of the body. Alcohol is a cooling agent; the large amount of warm blood in the skin rapidly loses heat. The increased heat production due to the oxidation of the alcohol in the body is quite inadequate to compensate for this loss of heat. When it is desired to increase directly the heat loss from the body and at the same time relieve congestion of internal organs and calm the nervous system alcohol may be used as an antipyretic drug: but the danger, now so well known, of the use of alcohol before exposure to cold must never be lost sight of.

Other Effects.

Apart from its reflex effects alcohol has singularly little action upon respiration; this question, after the careful work of Higgins,[6] may be considered settled. The same may be said of its action upon the kidneys. This, of course, does not imply that large quantities of alcohol, or alcoholic beverages containing other constituents, have no action on the respiration and kidneys; indeed, the contrary is the case, but this action has no bearing upon the use of alcohol as a drug. Upon the action, if any, of alcohol upon those small but important structures, the endocrine glands, we know nothing.

As to the influence of alcohol upon the various infection diseases, the possible concentration of alcohol in the blood, even in a state of intoxication, rarely exceeds 0·25 per cent., and 0·6 per cent. is usually fatal. This concentration is quite insufficient to have any antiseptic action upon pathogenic organisms. Alcoholic subjects with degenerated tissues are well known to fall easy victims to infectious diseases, and there is considerable evidence that even in non-alcoholic subjects a dose of alcohol will lower the resisting power to infection by the pneumococcus, *Streptococcus erysipelatosus*, *Staphylococcus pyogenes*, and probably *Diplococcus rheumaticus*.[10,11] There is some evidence that alcohol has some power to neutralise the toxins produced by the *Bacillus typhosus*, the *Bacillus coli*,[7] and the tubercle bacillus.[8,9] Much further work is required on this interesting and important subject.

The alcohol circulating in the blood is gradually burnt up in the body, and by its combustion it supplies heat and energy; as the rate of oxidation is comparatively slow it serves the purpose of a food for some considerable time, but with therapeutic doses 95 per cent. is burnt up in 24 hours and only 5 per cent. excreted. The amount which can thus be utilised is strictly limited, and an increase in the amount taken does not lead to a more rapid oxidation; for example, Higgins found that 45 c.cm. is not burned at a faster rate than 30 c.cm.—the former required 12 and the latter 8 hours.

The careful experiments of Neumann[12] have shown that alcohol up to 100 g. daily can replace a chemically equivalent amount of fat in the dietary. 1 g. of alcohol gives 7 calories, compared with fat 9·3 and sugar 4·1. As much as 40 per cent. of the carbohydrate needs of the body can be supplied by alcohol, and a still larger proportion in the case of a patient confined to bed.

The value of alcohol as a food must be discounted by its concomitant actions as a drug. There is no doubt that it is not a necessary food in health; whether it is a desirable food is largely a matter of opinion, but there can be no doubt that there are conditions of disease where its sedative action on the nervous system may be desired and where the digestive functions are in abeyance. Here a form of hydrocarbon of high calorific value, which requires no digestion, is quickly absorbed, and readily oxidised may be of very considerable value, and on this account alcohol may be preferred in such cases to other narcotics of greater potency, but which lack any nutritive properties.

Therapeutic Considerations.

I have now enumerated all the actions of alcohol which can be utilised in the practice of medicine; and powerful as these actions are I want to lay stress upon the fact that we have no proof of any direct stimulating action of pure ethyl alcohol upon the functions of the body after absorption. A substance which possesses such powerful actions may be approved or disapproved, but cannot be ignored as a drug, and our knowledge of the true place of alcohol in therapeutics would soon be largely increased if it were always prescribed with a definite aim and an exact idea as to what it was expected to do in any particular case, and not in that vague indefinite way in which it is sometimes the custom to order so-called stimulants.

For therapeutic purposes I should place the dose at the equivalent of from 20 to 180 c.cm. of pure ethyl alcohol in the 24 hours, and I doubt whether any further benefit can be obtained by more than the latter amount, even in subjects already habituated to alcohol.

The alcohol can often be prescribed with advantage as 50 per cent. alcohol (proof spirit) made up like any other powerful drug in a mixture with such disguising agents as tinct. gent. co., tinct. card. co., tinct. cinchon. co., or spir. chloroformi.

So far I have considered only the effects of pure ethyl alcohol, and I hesitate to enter upon the difficult and debateable ground of the actions of the various alcoholic beverages as compared with pure alcohol; for some purposes they may be better and for others worse owing to the presence of other constituents, but exact knowledge on these points is still lacking. These other constituents include a number of volatile substances, some the higher alcohols, and others the so-called ethers, of the constitution and action of which we know little; wines and beers contain in addition sugars, gums, organic acids and their salts, tannins, bitters, and colouring substances. How far and in what manner these substances modify the action of ethyl alcohol requires investigation.

In experiments upon animals the action of the potable spirits is essentially that of ethyl alcohol and proportional to their alcoholic content, therefore any difference observed in their action on man must be due to an action upon those brain centres which are not developed in the animals used for experiment. Part at any rate of the difference not infrequently noticed between the effects of different alcoholic beverages may be due to the specific stimulation of olfactory nerve-endings. We all know how extraordinarily powerful an odour is in reviving old memories and starting trains of association in our consciousness. Possibly some of the differences noticed in the relative effects of different alcoholic beverages may be due to the effects of the volatile odoriferous constituents arousing different trains of association.

I am of the opinion that it would be of advantage to the community if all distilled spirits were looked upon and used as drugs only.

A FURTHER INVESTIGATION INTO THE AGGLUTINATING PROPERTIES OF CERTAIN SERA AGAINST *B. TYPHOSUS*, *B. PARATYPHOSUS A* AND *B.*[1]

BY THOMAS T. O'FARRELL, F.R.C.S. IREL., D.P.H.,
FIRST ASSISTANT IN PATHOLOGY, UNIVERSITY COLLEGE, DUBLIN, N.U.I.

THE following is an account of the results obtained with 227 [2] sera of antityphoid-inoculated men tested by the Oxford method. The material was obtained from the same source as that which was the subject of a previous paper.[3] The sera had been sent from the Military Hospital, Portobello, to this laboratory, University College, Dublin, National University of Ireland, for the Wassermann test, and had been taken from men who had received antityphoid inoculation. None of these cases were suffering, or had recently suffered, from enteric fever. Information was procured as to the number of inoculations together with the date of last inoculation which the man had received, but no data as to the type of vaccine employed were obtainable. As regards agglutinins for *B. typhosus*, the results obtained with the sera of 269 inoculated men previously examined and reported on are included. The standard cultures were kindly supplied to me by the Director of the Standards Laboratory, Oxford, whom I have to thank for a very regular and liberal supply. The research was carried out under the supervision of Professor E. J. McWeeney, and I have to express my indebtedness to him for many valuable suggestions.

Agglutination Results with B. Typhosus.

In Table I. are set down the results obtained with 227 sera of the present series of cases together with 269 specimens which formed the subject of a previous communication. This gives in all the results of the examination of 496 sera of inoculated men. From this it will be seen that:—

1. The number of sera which failed to agglutinate Ty.,[4] designated as 0 units, increase as the time since last inoculation is prolonged—viz., 10·9 per cent., 11·5 per cent., 14·6 per cent., 12·8 per cent., 15·9 per cent., 24·0 per cent., 8·0 per cent. (few sera), and 23·9 per cent. at the various three months periods. It will be noticed that there is a sudden increase in the number of negative sera at the end of 15 months.

2. The highest number of units is obtainable during the first three months since inoculation, 4·8 per cent. giving 650–1250 units. After three months since inoculation no sera came into the 650–1250 units group, and only a small percentage, 0·9 per cent., came within the 350–650 unit group. This indicated a sudden drop in high titres after the third month. In the three groups 7–9. 10–12, 13–15 months —i.e., between the seventh and fifteenth month since inoculation, no serum reaches 350–650 units, but there are a good many (4 per cent., 4·6 per cent., 2·2 per cent.) to be found in the 150–350 unit group. After 16 months none of the sera reached the 150–350 unit group. As might be expected, as the number of sera giving high titres diminish, the figures for the lower titres increase—e.g., under the group 3–15 units, reading down, the figures in the column for the time periods since last inoculation are 9·7 per cent., 26·5 per cent., 24 per cent., 31·4 per cent., 45·4 per cent., 44 per cent. and 48 per cent.

From a study of these 496 sera it would appear that, in so far as agglutinins may be taken as an index to immunity against infection, during the first three months since inoculation immunity is high, from 4–15 months it is moderate, and after 15 months it is poor. After 15 months the number of negatives increases, and among the positive sera the titres are low. To secure immunity, therefore, the inoculation should be repeated after the lapse of not later than 15 months.

The Effect of Multiple Inoculation with B. Typhosus *Vaccine.*

A chart was constructed giving the agglutination results obtained with *B. typhosus* with the sera of men who had been inoculated once, twice, and three or more times. The chart would seem to show that (1) fewer non-agglutinating sera are met with in multiple inoculation, particularly during 16–24 months after inoculation; (2) multiple inoculation does not produce such a high response as the first single inoculation, but, on the other hand, in the sera of men who have been inoculated several times a high agglutinin content is persistent. The result of one inoculation might be compared to the brilliant, though not permanent, effect of a large single dose of salvarsan in a case of syphilis, as compared with the slow, but more permanent, improvement brought about by smaller doses frequently repeated.

The Effect of Typhoid Mixed "T.A.B." Vaccine on the Typhoid Agglutinin Titre.

It is stated in the directions issued with the Oxford standard cultures that an attack of paratyphoid fever may raise, either slightly or markedly, the artificial typhoid agglutinins already present in the serum of an inoculated individual, apart altogether from the production of specific paratyphoid agglutinins. Arising out of this statement the question presents itself—granting that a man has already received *B. typhosus* vaccine, if he be now injected with mixed T.A.B. vaccine, will his artificial typhoid agglutinins be raised to a higher point and will they become more lasting than if he had received a second dose of simple *B. typhosus* vaccine only? If this were the case, inoculation with T.A.B. vaccine would be actually preferable.

Unfortunately, in the present series of cases no details as to the type of vaccine employed for inoculation were obtainable, but it perhaps may be fairly assumed that the men whose sera agglutinated A or B, or both, as well as Ty. had received mixed T.A.B. vaccine, whereas those which agglutinated Ty. only, had only received simple Ty. vaccine. None of these cases had a history of recent typhoid or paratyphoid fever, so that the presence of natural agglutinins could be excluded.

With the above point in view Table II. has been drawn up. The sera are arranged under four heads: (1) Those sera which agglutinated Ty. only; (2) those which agglutinated both Ty. and A; (3) those which agglutinated Ty. and B; and lastly (4) those which agglutinated all three. The sera which failed to agglutinate any of the micro-organisms have been omitted from the list. The figures in these columns indicate the average agglutinin units (i.e., the total number of units divided by the number of sera examined) for Ty. in all cases, and they are further arranged according to the number of months since last inoculation.

It will be noticed that the Ty agglutinin content is higher in mixed vaccine cases, at practically all periods, than was obtained in cases inoculated with simple Ty. vaccine (first column). This marked difference between the Ty. agglutinin content of sera of persons who had received simple Ty. vaccine and mixed T.A.B. vaccine may be due (1) to the typhoid element in T.A.B. vaccine; (2) to the A and B elements together; (3) to the A or B elements individually.

Before determining whether this relatively high Ty. agglutinin content is due to the A or B constituents it is necessary to make sure that we are not comparing, in the first column, the sera of men who have received but one dose of Ty. vaccine with the sera of men in the other columns, who have, in all probability, received the T.A.B. vaccine as a second dose (T.A.B. inoculation having been introduced at a much later

* Since last inoculation.

period than simple Ty. inoculation), because in this event (as has been shown before) cases who have received two doses of Ty. vaccine would have a higher unit content than those who had received only one dose, apart altogether from the question of A and B constituents.

In drawing up Table II. due attention has been paid to this point and only the sera of men who have received more than one inoculation have been included, so that the excess of Ty. agglutinins in the T.A.B. cases cannot be ascribed to the difference in effect which would be produced by two doses of Ty. vaccine over that produced by one dose only. The elimination from the table of all cases who had received only a single dose of vaccine reduces the total number of cases to a considerable extent. Further accuracy might be obtained if cases who had received two doses of vaccine and three doses of vaccine respectively were compared, but the relatively small number of cases would not allow of any further subdivision.

Now, granting that the Ty. element of the T.A.B. vaccine is not responsible for this increase in Ty. agglutinins, it must be due to the A or B element, or both equally, or to their combined presence. Although the number of cases have become smaller when so many factors have to be taken into consideration, the figures would seem to point to the fact that the combined presence of the A and B elements is responsible for the rise in the Ty. agglutinin titre. From the figures available it would not be possible to say whether the A and B elements taken individually can claim priority in causing this effect.

Agglutination Results with B. Paratyphosus A *and* B.

The results obtained are set out in Tables III. and IV. On the whole, these results are disappointing, as a large number of sera failed to agglutinate either A or B. This

may be partly explained by the absence of the A and B elements in the vaccines in the case of men who had received inoculation more than 12 months before the examination of the sera was made; but one would expect to get more sera agglutinating A and B among those men who had been comparatively recently inoculated, say within 12 months, when inoculation with mixed T.A.B. vaccine had become more general.

Two other factors which might produce this poor response may also be taken into consideration: 1. The dose of A and B in mixed T.A.B. vaccine is only half the strength of the Ty. 2. The agglutinins resulting from an injection of T.A.B. vaccine would greatly favour the Ty. agglutinins in the case of a man who had already been inoculated with simple Ty. vaccine; that is to say, the A and B elements in the vaccine might be only the first dose of these particular micro-organisms, and consequently their agglutinins would fade away more quickly from the serum, whereas the Ty. element in the vaccine might represent the third or fourth dose of this microbe; consequently the agglutinins would persist for a longer time in the serum.

This extraordinary discrepancy between Ty. and A and B agglutinins was well seen in a chart where the percentage of negative sera obtained with Ty., A, and B are set out. So far as these cases are concerned one would be inclined to say that A and B agglutinins begin to disappear rapidly three months after inoculation; after twelve months they are practically gone, except in the case of A, where they persist longer than B agglutinins. As even in Ty.-inoculated subjects one must be prepared for a certain number of non-agglutinating sera, what might be regarded as the normal negatives, so also in the case of A and B inoculation a certain number of sera will be met with which will not agglutinate A and B.

In the absence of any definite information as to the type of vaccine the men of this series had received, it might be well to examine what might be termed the positive side, and compare those sera which agglutinated each micro-organism, eliminating from the figures those sera which were negative.

When entering into a criticism upon the relative properties of sera which agglutinate Ty., A, and B, it must be remembered that although the cultures used in this investigation were Oxford Standard Cultures, these standards only hold good for repeated examinations with one specific micro-organism. The cultures were not standardised as against each other. A standard unit of Ty. agglutinin does not necessarily correspond with a standard unit of A or B agglutinin. The sera which form the subject of this paper were tested against standard cultures which had the average factors of 5·7 for Ty., 3·6 for A, and 3·0 for B. It should be remembered, therefore, that the course of the curves rather than their relative heights are compared.

A chart has been drawn up so as to compare the sera which agglutinated Ty., A, and B. All negative sera have been eliminated, and the percentages calculated upon the number of sera which agglutinated the three micro-organisms.

The following observations may be made:—1. During the 1–3 months period after inoculation the A agglutinins approximate much more closely to the Ty. agglutinins than do the B. The agglutinins for B are much weaker—viz., more weak titres (3–15) and less high ones, the highest number of units reached being 35–65. 2 During the 4–6 months period the Ty. curve is comparatively stationary, whereas those for A and B are both decidedly weaker, the curves being steeper. 3. During the 7–9 months all three curves show weakness, but the curve for A agglutinins has still some similarity to Ty. agglutinins as regards high titres; but a larger percentage of cases gave only 3–15 units. 4 During the 10–12 months period the Ty. agglutinins are holding their ground, whereas A and B are both falling away together, the difference being possibly slightly in favour of A agglutinins.

An examination of the curves would seem to indicate that the A agglutinins behave like those for Ty. The B response is weak all the time. In T.A.B. vaccine the dose of A is only half the strength of the Ty., and it would appear justifiable to conclude that if the same dose of A vaccine were given as is given for Ty. the resulting agglutinins would be the same and the immunity as estimated by agglutinins would be equally good.

But in the case of B agglutinins the response to vaccine, as at present used, is comparatively so weak that a considerably stronger vaccine would be necessary to produce an equally strong immunity. Consequently, one would be tempted to recommend a change of dosage in prophylactic T.A.B. inoculation—namely, to equalise the strength of A element with that of Ty. and to give twice the corresponding strength of B vaccine. The ratio then would be Ty.^{1}, A^1, B^2. This might suitably be given in three doses.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

Morbid Anatomy and Histology of Rheumatoid Arthritis.

A MEETING of this society was held on Oct. 28th, Major A. F. VOELCKER, the President, being in the chair, when Dr. T. S. P. STRANGEWAYS read a paper on the Morbid Anatomy and Histology of Rheumatoid Arthritis, and exhibited numerous pictures on the epidiascope showing the inflammatory and fibrotic conditions around the joints.

Dr. STRANGEWAYS gave the following summary of a report with a detailed description of the changes found in joints of patients suffering from that form of chronic arthritis at present recognised clinically as rheumatoid arthritis. Most of the specimens which furnished the material for the report were obtained during post-mortem examination of over 2000 joints of patients suffering from one or other of the following forms of chronic arthritis—namely, rheumatoid arthritis, osteo-arthritis, chronic gout, or Charcot's disease. He was indebted to a large number of men in practice in Great Britain and Ireland for the clinical and pathological material from which this report was prepared, and wished to express his gratitude to them for allowing him to conduct the post-mortems necessary. The anatomical and microscopical specimens prepared to demonstrate the various changes in such joints were preserved at the Cambridge Research Hospital, where they were accessible for inspection to any interested. The report referred to was submitted to the Medical Research Committee, who made a generous grant in aid of the work from the funds at their disposal. The summary has been written in the form of categorical statements, which for the sake of reference have been numbered.

Changes found in Rheumatoid Arthritis.

1. The term rheumatoid arthritis, as at present used, includes several forms of arthritis which are clearly due to different causes, although clinically they may show several points of similarity.

2. The crippling and deformity associated with rheumatoid arthritis or what is taken as such is largely of muscular origin which may be (*a*) of the nature of an involuntary contraction brought about by pain referred to the joint of the crippled limb, (*b*) due to an involuntary muscular spasm caused by pain on movement of the damaged joint, (*c*) due to actual atrophy and shortening of some of the muscles connected with the diseased joint. This atrophy is usually associated with disuse and long-continued muscular spasm.

3. In other cases the deformity is due to changes in the joint itself such as: (*a*) distension of the capsule by an excess of synovial fluid, (*b*) dislocation of the bones of the articulation, (*c*) changes in the shape of the articular surfaces owing to formation of new bone or to erosion of the original.

4. Some cases in which clinically the joints appear to be damaged show very little morbid change on post-mortem examination, although the symptoms of arthritis with crippling deformity have been present for many years. Some of these cases seem to be of nervous origin, associated with pain which is referred to the joint.

5. Cases are observed in which the capsule of the joint has been distended for a long period by an excess of synovial fluid, accompanied by more or less deformity, but in which on post-mortem examination no marked changes are discovered. In some examples of this type the fluid ultimately diminishes. Fibrotic changes may then be present in the capsule and the articular cartilages may have undergone fibrillation or atrophy.

6. A considerable proportion of the joints show distinct inflammatory changes in the synovial membrane, in the capsule or in the bones of the articulation; in any case the articular cartilage may be involved. These inflammatory lesions may be present in one or all of the above-mentioned structures, and be either acute, subacute, or chronic.

7. In a few cases the processes are obviously of infective origin and are associated with marked inflammatory changes in the synovial membrane and the formation of thick fleshy villi and vascular adhesions. Microscopically, the inflamed tissues show large collections of inflammatory cells and new capillaries. Erosion of the articular cartilage and bones may also be present.

Nature of Inflammatory Process.

8. If changes are found in a joint affected with what is termed rheumatoid arthritis they are usually of an inflammatory nature, but their severity and extent vary considerably in different cases and in different joints from the same case. The changes may be present in a part only of the articulation.

9. The inflammatory process may originate either in the synovial membrane, in the capsule, or in the medulla of the superficial cancellous spaces of the epiphysis, or in all three of these structures.

10. The inflammatory process, if severe, is associated with proliferation of the connective tissue cells, the development of new blood-vessels, the accumulation of leucocytes, and sometimes with the extravasation of red blood corpuscles and the presence of fibrin. The inflammatory tissue may originate in the synovial membrane or in the capsule and invade the articular cartilage and bone, or lead to the formation of inflammatory adhesions in the joint cavity. This inflammatory tissue tends in the course of time to become organised and converted into fibrous tissue and may result in fibrous ankylosis either between the adjacent surfaces of the capsule or between the cartilage, or even between the bones of the articulation if the original cartilage has been destroyed.

11. In some cases the arthritis is of a subacute type from the onset, and the inflammatory changes, although often progressive, are not so marked. In this type the changes may originate in the synovial membrane, the capsule, or the superficial marrow spaces of the epiphysis, from either of which they may spread to the articular cartilage; the process leads to the formation of fibrosing tissue in the affected areas, and this when present in the capsule causes the latter to contract. The movements of the limb are in consequence restricted and the articular cavity decreased in size. Fibrous adhesions also develop in these joints, and in some cases fibrous, cartilaginous, or bony ankylosis.

12. The changes in the superficial marrow spaces lead to resorption or erosion of the osseous trabeculæ, which may be associated with the invasion and replacement of the articular cartilage by the inflammatory tissue.

13. Other joints show a slowly progressive inflammatory fibrosis of the capsule, often associated with degenerative changes in the cartilage and proliferative changes in some of the superficial marrow spaces. In these joints areas of cartilage may be invaded, either superficially from the capsule or from beneath by proliferating connective tissue cells and new vessels of the superficial marrow spaces.

14. The inflammatory reaction of the marrow of the superficial cancellous spaces of the epiphysis may be of an acute, subacute, or chronic type. In either type the connective tissue cells of the marrow proliferate and new blood-vessels form. In the acute cases the new connective tissue cells are of stellate form. In the chronic cases the connective tissue cells appear more fibroblastic, especially such as be near the edges of the bone trabeculæ, but in all cases these cells show a tendency to store up fat and become marrow cells as the inflammatory process subsides. In those cases where the superficial osseous trabeculæ are eroded and the zone of calcified cartilage invaded the connective tissue cells and vessels form a definitely organised fibrotic tissue, the cells of which do not show the same tendency to produce fat.

15. In no instance has it been possible to demonstrate periarticular changes of an inflammatory nature around the affected joints, and it is doubtful if there is such a condition as periarticular rheumatoid arthritis.

Changes in Cartilage.

16. The changes in the cartilage vary considerably in different joints from the same case, and even in the same joint.

17. The articular cartilage may show signs of atrophy, accompanied by modifications in the staining reaction of the matrix.

18. The articular cartilage may show proliferation of its cells, which results in the formation of cell groups usually surrounded by an unstained zone.

19. The cartilage may become definitely fibrillated, and with this change there is usually evidence of proliferation and the formation of groups of cartilage cells. The fibrillation begins, as a rule, on the free surface and may extend to the deepest parts of the articular cartilage.

20. The hyaline cartilage may become converted into a modified fibro-cartilage, but in such specimens there is usually evidence of some inflammatory process in the neighbourhood of the altered structure. This process seems to be due to proliferation of the cartilage cells, but in some specimens the connective tissue cells of the inflammatory tissue also appear to take part in the formation of fibro-cartilage.

21. Areas of the articular cartilage may become necrotic; this necrosis may be found where inflammatory reaction has taken place. The edges of the necrotic mass often show a beautiful replacement fibrosis, which may eventually lead to the complete removal of the necrotic tissue.

22. In some joints portions, or even the whole layer, of the articular cartilage may be infiltrated and replaced by a more

or less vascular inflammatory tissue, owing to the cartilage having been invaded by new blood-vessels and connective tissue cells. In certain specimens the cartilage cells proliferate and appear to take part in the formation of the new tissue which has replaced the cartilage. This replacement of cartilage may begin either on the free surface from an inflammatory process spreading from the synovial membrane or capsule, or in the deeper parts of the cartilage by the extension of an inflammatory process from the subadjacent marrow spaces.

Changes in Bone.

23. The articular bone may show atrophy, rarefaction, resorption, or erosion.

24. The superficial osseous trabeculæ underlying those portions of the articular cartilage in which advanced atrophy, fibrillation, or complete wearing away has taken place may show increase in size and density owing to formation of new bone, brought about by continued use of the limb notwithstanding the joint changes. The amount of the new bone formed appears to depend upon the reaction of the tissues to pressure, and this increases in proportion to the weight and friction on the affected area. In those instances where the cartilage is absent and the superficial bone exposed this process leads to polishing of the superficial surface of the sclerosed bone. Associated with this increased density of the osseous trabeculæ minute fractures are often seen; these are probably of traumatic origin. In the neighbourhood of these fractures there is generally callus formation, with a combined process of resorption and repair around the injured area. These changes are characteristic of osteo-arthritis, but are not common in rheumatoid arthritis.

25. In those instances in which the inflammatory changes are confined to the synovial membrane active changes are not observed in the bone marrow or osseous trabeculæ, but there is often atrophy of the osseous trabeculæ in the neighbourhood of the affected joint; this appears to be due to disuse.

26. When an inflammatory process attacks the articular cartilage or bone of a joint inflammatory changes do not, except in rare instances, involve the whole of the epiphysis, but are usually strictly confined to the quite superficial cancellous spaces and superficial osseous trabeculæ. As a rule these changes are not found over the whole of the articular surface, but only in isolated areas; they vary greatly in intensity and extent in different joints or in different parts of the same joint. The process may be a chronic, slowly progressive resorption of bone, accompanied by new formation of bone in the neighbourhood. In such areas very few or no multinucleated osteoclasts are observed. When the process is more active proliferative changes are found in the bone marrow, with congested blood-vessels, osteoclasts, and inflammatory cells. This process often leads to erosion of the articular cartilage and the underlying bone; with very rare exceptions the formation of new bone can be seen taking place in the affected area. In some cases the resorption of bone is more rapid than the new formation, in others formation of new bone is in excess.

Development of New Bone.

27. The development of new bone in a damaged joint may take place (*a*) in the articular cartilage, (*b*) in altered articular cartilage, (*c*) in the zone of calcified cartilage, (*d*) on the edge of pre-existing bone trabeculæ, (*e*) in inflammatory connective tissue in the cancellous spaces, (*f*) in fibrous adhesions.

28. The development of new bone in hyaline cartilage may be due to changes in the cartilage cells; these changes are usually preceded by vascularisation of the affected area and by a deposition of calcium salts in the surrounding matrix. This is followed by proliferative changes in the cartilage cells and the gradual development of new bone from the modified cartilage cells.

29. The development of new bone in altered hyaline cartilage—for example, fibro-cartilage—may occur through changes similar to those described in the hyaline.

30. The development of new bone is sometimes seen in areas of vascular inflammatory tissue which has invaded and replaced a portion of the articular cartilage. The new bone in this case may either be formed by cartilage cells, as above described, or from the connective tissue cells of the inflammatory tissue.

31. The development of new bone in the zone of calcified cartilage may be due to changes similar to those described in the hyaline.

32. In rheumatoid arthritis the development of new bone on the edges of pre-existing bone trabeculæ is usually accompanied by proliferative changes in the marrow, which lead to resorption of bone in the neighbourhood of the new formation. The two processes occur simultaneously, and appear to depend upon some irritant causing increased blood-supply, which brings about resorption, and to pressure on the affected area from use of the limb, which causes the development of new bone.

33. Where new bone develops in inflammatory tissue which has replaced the marrow and osseous trabeculæ it appears to be formed from connective tissue cells in this inflammatory tissue.

34. New bone in fibrous adhesions appears to be formed from the connective tissue cells of the fibrous tissue.

35. In all the above instances the development of new bone is associated with the formation of cancellous spaces and marrow tissue. The new marrow usually consists of adipose tissue. The formation of the cancellous spaces appears to be due to the development of new blood-vessels, to changes in the vascular supply, and to the development of stellate connective tissue cells in which fat accumulates.

Limitation of Movement.

36. Limitation of movement in a joint may be due to (*a*) muscular spasm, (*b*) shortening and atrophy of muscles and tendons, (*c*) fibrotic changes in the capsule leading to contraction, (*d*) alteration in shape of the articular surfaces, (*e*) ankylosis, which may be fibrous, cartilaginous, or osseous.

37. Where the limitation of movement in a joint is due to muscular spasm it can be overcome by deep anæsthesia, but it returns when the effect of the anæsthetic has passed off.

38. The passive movement of a joint in which shortening and contraction of the muscles and tendons is suspected should not be lightly undertaken, as it is often associated with fatty changes in all the tissues of the joint, and fracture of any or all the tissues round the joint may take place.

39. Fibrotic changes in the capsule associated with contraction may be so extreme that the joint cavity is completely obliterated and the joint surfaces lie in close contact with the fibrous capsule, moulded tightly around the articulation.

40. Fibrous ankylosis is due to adhesions formed by the organisation of inflammatory tissue, which may originate either in the synovial membrane, the capsule, or in the superficial marrow spaces. These adhesions may partly or completely occlude the joint cavity. They may consist of long processes of more or less vascular fibrous tissue, which thus allow limited movement to take place in the joint, or of dense contracted fibrous tissue which firmly unites the articular spaces of the two bones (fibrous ankylosis).

41. The articular cartilage may become ankylosed by the matrix of the two layers of the hyaline cartilage becoming fused into one continuous layer, or the two layers may unite and be transformed into a modified fibro-cartilage. The ankylosed cartilage may become necrotic, and is often invaded and replaced by an inflammatory fibrous tissue, or new bone may develop in the ankylosed cartilage and thus bring about osseous ankylosis.

42. Osseous ankylosis takes place by the development of new bone either in ankylosed cartilage or in the fibrous tissue which has already produced fibrous ankylosis.

43. Ankylosis may occur between the two zones of calcified cartilage, but this form of fusion shows a tendency to become replaced by one of true bone.

Villous Outgrowths.

44. Villous outgrowths are found in some joints. These may be due to (*a*) overgrowth of normal villi, (*b*) inflammatory changes in the synovial membranes or in the capsule.

45. Villous outgrowths in a joint may consist of (*a*) vascular fibrous tissues, (*b*) dense fibrous tissue, (*c*) fibrous tissue enclosing groups of fat cells; (*d*) inflammatory tissue with dilated capillaries and groups of inflammatory cells, (*e*) degenerated or necrotic tissues, (*f*) connective tissue showing vessels deeply congested owing to obstructed circulation.

46. Villous outgrowths may become detached by rupture of the fine pedicles and so form a loose body in the joint cavity. The detachment may be preceded by necrosis.

47. Microscopic villi formed of cartilage are occasionally found on the surface of altered articular cartilage. These may be formed of hyaline or fibro-cartilage.

48. No constant changes are found after death in the organs or tissues of patients who have suffered from rheumatoid arthritis.

Discussion.

Dr. A. P. BEDDARD, in discussing the treatment of the condition, said that all joint affections, with the exception of gout, were due to infection. In order to treat the condition we must first find out where the infection came from and then investigate its bacteriology. In his opinion, in about 90 per cent. of the cases the infection came from the teeth and gums. It was impossible to say what the state was of the deep tissues of the mouth after a superficial examination; the use of X rays was absolutely essential. The attitude of dentists was fundamental, for they usually denied that the gums were infected unless there was running

pus. We must have common ground between the medical and dental points of view, and there was an enormous field for the education of the two professions in this connexion. Of the other 10 per cent., the infection in a few possibly came from infected tonsils and adenoids. A few also were due to infection of the mucous membrane lining the female genital organs after pregnancy. Curetting an infected uterus was of no use and might lead to the dissemination through the body of a large dose of bacteria. He had seen an extensive outbreak of joint trouble after curetting. It might be needful to remove all the female genital organs if such an operation should prove absolutely necessary. Infection of the alimentary tract was rarely a primary state of things. There was usually a previous *Streptococcus longus* infection of the teeth and gums, or tonsils and adenoids. After the primary cause was removed the question arose as to how to deal with the secondary manifestations. As far as the alimentary tract was concerned, where there were no signs suggesting that the mucous membrane of the colon was infected (such as attacks of diarrhœa) this was not likely to be the cause of the chronic arthritis. Dieting and washing out the colon were not of much use. With regard to partial or complete colectomy, he said that however complete the operation was the infection was not cured, and the operation was an extremely dangerous one. The removal of colons in highly infected people led to formation of adhesions in about six months. Wherever there was an infected tube which could not be cured it was first necessary, by the use of X rays, to see if there was any mechanical difficulty. In this case, and if an operation was to be performed, it was essential to produce less mechanical difficulty than was already present—in other words, the less done the better. The obvious treatment for the joints was vaccination, in order to stir up the body to the point of combating the infection. Of the usual bacteria present, about 75 per cent. were *Streptococcus longus*, and these, together with the pneumococcus and gonococcus, accounted for about 99 per cent. All three organisms might be found. In order to find out which was the offending organism, it was necessary to make vaccines of each and see which, on injection, would produce a good reaction —i.e., pain in the joints. He had known a lady from whom many strains of streptococci were isolated, but in whom only those from the teeth caused joint pain. Vaccine treatment was a question of a year or years, and should be continued till no pain could be produced in any joints on injection. This only referred to inflammatory and not mechanical effects. Ionisation, baths, &c., were only useful to relieve pain. It was "up to" the medical profession to standardise the treatment at health resorts. Massage was useful in keeping up movements, but could do little good with very stiff joints. The real treatment was preventive. With regard to the surgical treatment of infected joints, we must remember that the lower limbs must carry the weight of the body. Forcible movement of still infected joints was a great mistake. To get a permanently mobile useful joint was a matter of years, and with hospital patients (who probably would not persist with treatment) it was better to give up all idea of freely movable joints and go in for fibrous ankylosis.

Dr. M. J. ROWLANDS said that he had been enabled to carry out an investigation of rheumatoid arthritis among soldiers at Netley. He did not agree that such a large percentage were due to *Streptococcus longus*. Infection was generally due to *B. coli*. The gonococcus was present in a large number of cases. He was convinced that the disease was a toxic disease—a trophic neurosis—and until we could find out where the infection attacked the nerve we could never promote cure. He was much opposed to spa treatment and had never known a case to be cured by such. Hyperæsthetic areas around acute joints were very noticeable, and the pin-prick or pulling of hairs could be used to show if the joint was or was not in an acute stage. A large number of paratyphoid patients returned from Salonika had developed rheumatoid arthritis.

Dr. F. DE HAVILLAND HALL said that patients had expressed relief after taking sulphur and guaiacum. Many were anæmic, and for these iron and arsenic, with or without strychnine, were needed. X ray examination of the mouth and the elimination of *B. coli* infection were most important.

Mr. V. WARREN LOW, Dr. G. DRUMMOND ROBINSON, and Dr. F. PARKES WEBER also spoke.

Reviews and Notices of Books.

Prothèse et Chirurgie: Cranio-maxillo-faciale. By J. LEBEDINSKY and M. VIRENQUE. With 154 plates, comprising 421 illustrations. Paris: Baillière et Fils. 1918. Pp. 398. £1 1*s*.

THIS volume embodies the clinical experience and teaching deduced from the treatment and plastic repair of wounds involving the jaws, face, and cranial vault at the Military Hospital of Le Mans. It approaches the dimensions of a standard work on this comparatively new branch of surgery. The authors have made a complete survey of the field, and their results show once again the great value of the prosthetist and surgeon working in mutual alliance. The compilation is the work of masters of their craft, for we must bear in mind that the injuries described were seldom encountered before the war, and the literature dealing with them was meagre and of slight clinical value. A salient feature in their scheme of treatment is the "osteo-periosteal graft." It may be described as the theme of the work. Employing the technique elaborated by Delagenière, the authors use it for the repair of all skeletal losses. The relative value of this type of graft, in contra-distinction to grafts of full thickness of bone or cartilage, is discussed at great length, the authors taking as their standpoint the theory that the periosteum preserves its vitality and acts as an osteogenetic focus. In support of this assertion they speak of a thin, viscid, slightly yellow secretion which is occasionally observed escaping from the wound after the insertion of these grafts. This they assume to be a true periosteal secretion. They also adduce as further evidence the fact that, in spite of the occasional exfoliation of the compact tissue of the graft, bony union has yet been obtained, although somewhat delayed. The microscopical evidences of the pathological processes occurring in the grafted area, relative to the absorption and deposition of new compact bone, are also discussed. It is asserted that the additional osteogenetic surface given by the periosteal layer is the main factor in retaining continuity of the graft, particularly in those cases presenting considerable loss of bone. Our experience of these grafts, although limited to their use in the treatment of pseudarthrosis of the mandible, with but slight loss of bone, supports the authors' high opinion of the osteo-periosteal graft. Their own results on the mandible are sufficiently encouraging. Out of 15 cases of pseudarthrosis treated by this method, some with very considerable loss of bone, 9 have been absolutely successful, 2 showed slight mobility only at the end of five months, 1 failed owing to the refusal of the patient to submit to immobilisation, while 3 are of recent date and hold out every prospect of a complete cure.

The results of the same method of grafting in the repair of cranial injuries, and for the restoration of facial contour, are equally satisfactory. In all cases the technique employed is the same. Laminæ of periosteum containing the subjacent layer of compact bone are lifted from the inner aspect of the shaft of the tibia by means of a chisel. The ends of the bony fragments to be grafted are cleaned and freshened. Retention pockets for the reception of the extremities of the graft are made by lifting the periosteum off the fragments by means of elevators. Into these retention pockets the extremities of the grafts are wedged. Depending on the area to be covered one or more grafts are used, overlapping each other in the cranial defects, whereas in the mandible they are placed in the following manner: one in relation to the freshened inner aspect of the fragments; the second external; while a third is laid in contact with the other two between the fragments. No foreign bodies whatever (with the occasional exception of catgut) are used to attach the grafts. The jaws are not immobilised until 12 hours after the operation in order to allow the patient to recover from the effects of the anæsthetic. Drainage is dependent on local conditions and the extent of the area grafted. Immobilisation is complete for two months; full union occurs in from three to five. The length of the waiting period before grafting should be attempted is fully discussed, and successful cases are cited where the grafts have been inserted in the mandible at periods of 3½ or 4 months after date of wound. These grafts are also used, in combination with those of cartilage or fat,

for the obtaining of contour in the plastic repair of facial deformity. Attempts have even been made to repair the walls of the frontal and maxillary sinuses.

Fractures of the maxillæ are classified at great length and praise is due for the way in which these difficult conditions have been handled. One cardinal factor is insisted upon in the treatment of all cases—i.e., the restoration of normal occlusion. Opinions differ with regard to the advisability of making the attempt where bony loss has been sustained, but it may well be that in the surgical treatment of these fractures lies the key to the authors' success. The following statistics are quoted: Out of a total of 280 cases under treatment only 3 with vicious union occurred; pseudarthrosis resulted in 23 others, these latter cases, however, had suffered extensive loss of bone. The pages abound with descriptive illustrations, casts and splints being portrayed in great variety, the latter showing a truly Gallic ingenuity. The construction of splints is based on two main principles—the use of traction by rubber ligature for the correction of displacement, and the adaptation of guides and trolleys, to hold the jaws in normal occlusion after reduction. For the most part the methods advised are simple and there is an agreeable absence of cumbersome appliances, but we disagree with the authors in their contention that surgical methods for the correction of displacement are contra-indicated, as excellent results have been obtained from their use in selected cases.

With regard to the surgical aspect of these fractures, one innovation is made on what is now considered established practice. In cases with comminution the principle is laid down that only those spicules of bone lying in semi-attachment to the main fragments should be retained, the mobile spicules—i.e., with feeble periosteal attachment—being regarded as incipient foreign bodies and their removal indicated. If left, these form an obstacle to the formation of good callus. The repairing elements are regarded as the fixed adherent spicules, the flaps of periosteum, and the bony extremities, the intervening spicules giving rise to pseudarthrosis by causing a condensing osteitis with resulting eburnation of the main fragments. Efficient drainage is insisted upon as a necessary principle of treatment during the evolution of callus. Trismus is dealt with at length and is regarded, with few exceptions, as due to a hypertonicity of the elevator muscles, occasioned by reflexes following injury in the masseteric region. The relative feebleness of the depressor muscles of the mandible predisposes to this condition, which is accentuated by the poor nutrition following the injury. All cases of muscular origin have been cured by the use of a dilator instrument invented by the authors, tension being obtained by powerful elastics, the average duration of treatment being two months. This dilator is also used as a basis for reduction preliminary to splinting.

Some disappointment may be felt in reading the section devoted to plastic work, inasmuch as it lacks the detail given to the treatment of the jaw injuries. Sliding flaps are preferred where possible, contour being subsequently obtained by the insertion of osteo-periosteal, cartilage, or fat grafts, either singly or combined. The lip plastics are performed over a prosthesis. Double epithelialised flaps are mentioned, but these are the exception, and some surprise may be felt that they are not more extensively used, especially when the facial sinuses are exposed. This objection particularly applies to the cases of rhinoplasty where the inner aspect of the flap is exposed in a septic cavity, with the risk of suppuration and contraction.

The chapter on rhinoplasty is deficient in that it deals only with injuries involving the middle third of the nose. In those cases where the nasal cavities have been exposed, owing to the destruction of the overlying tissues, the authors make use of glass tubes, taking their purchase from the frontal region and resting on the upper lip, for retaining the air passages patent and as a means of preventing the upward displacement of the alæ. We have already made our criticism of the single-flap method of repair which is used in these cases. No mention is made in the chapter on plastic surgery of skin-grafting, an invaluable adjunct in this work, particularly in the form of the "Esser" epithelial inlay, which method has no equal in the treatment of ectropion and as a means of creating sulci for the better retention of dentures. There is a valuable suggestion culled from Morestin's work with regard to the surgical treatment of facial paralysis. This consists in the suturing of little tongues from the masseter and temporal to the peribuccal and the orbicularis palpebrarum muscles respectively. Much of interest also lies in the chapter devoted to salivary fistulæ. The theory advanced is that many of these fistulæ heal spontaneously by the suppression of glandular function. Ligature of Stenson's duct and alternatively avulsion of the secretory nerve to the parotid gland, the auriculo-temporal, are recommended as the best methods of treatment in intractable cases.

Many other matters of detail are usefully dwelt upon, including injuries of the nerves and blood-vessels, and the management of wounds involving the soft tissues of the face. We have here simply outlined the salient features of the volume. We strongly recommend the study of the book as a whole to those engaged in prosthesis and plastic surgery.

Précis de Dermatologie. By J. DARIER. Médecin de l'Hôpital St. Louis. Paris: Masson et Cie. 1918. Pp. 864. 18 francs.

THE name of Darier on the title-page of a text-book on dermatology guarantees to the reader both efficiency and originality, and the hospital of St. Louis has for many years attracted students from all parts of the world. No other hospital has produced such a number of distinguished dermatologists; at no other hospital has the dermatologist such unrivalled opportunities for study.

The first edition of this "Précis de Dermatologie" was exhausted some years ago, but the heavy duties entailed by the war prevented Dr. Darier from undertaking the publication of a new edition until now. Twenty years of further experience as a teacher has enabled him to compile a text-book admirably adapted to the needs of the advanced student and the practitioner. Practical points are dwelt upon; diagnosis is carefully and systematically described under every malady; theory and disputed problems are avoided. In his preface Dr. Darier claims that he has brought his new edition completely up to date, in line with the progress of science, yet without overburdening the text. Reference throughout proves the justice of this claim, and on turning to sections such as those dealing with anaphylaxis, cutaneous diphtheria and leukæmia, and syphilis we find examples of the precision, order, and compression for which French authors are justly famed. Treatment is indicated at the end of each section; details, with prescriptions, are to be found at the end of the volume. The British practitioner will note with interest the thoroughness and the length of the treatment of syphilis. At the outset Dr. Darier advises a course of 4 to 7 injections of novarsenobenzol, at weekly intervals, in doses of 0·30 g. to 0·90 g. After a pause of a few weeks mercurial injections are begun. Grey oil is preferred, and is administered in courses of six injections every two or three months for two years, and the result is better if this method is followed also during the third and fourth years. In strong subjects the mercury may be given at the same time as the arsenobenzol. The significance and limits of the Wassermann reaction are discussed.

In every malady described we find evidence of the extensive knowledge acquired only after long years of experience and persevering study devoted to a special subject. We recommend the work to the British medical profession.

A Text-book for Midwives. By J. S. FAIRBAIRN, B.M.Oxon. Second edition. London: Oxford Press Warehouse. 1918. Pp. 350. 20*s*.

THE author of this work has for many years been a teacher of midwives and closely associated with all movements for their higher training. The book in its new edition is much more than a mere text-book: it is a comprehensive exposition of the subject of midwifery adapted to the difficulties and the growing responsibilities of the present-day midwife. The introductory chapters on physiology are illuminating in the sense that they will really help the midwife to understand the phenomena which she has such abundant opportunity of observing. While all the special sections should be carefully studied, the section dealing with the duties of the midwife will be found specially useful, and we note the addition of a new chapter on antenatal care. A welcome feature of the book to the practising midwife will be the chapter summarising the rules of the Central Midwives Board, wherein she will recognise the work of a friend who enters into her difficulties with understanding.

The midwife who masters Dr. Fairbairn's book will not only make herself efficient in her craft but will become a useful handmaid to medicine.

LIBRARY TABLE.

The Megalithic Culture of Indonesia. By W. J. PERRY, B.A. London: Longmans, Green and Co. Manchester: At the University Press. 1918. Pp. 198. 12*s.* 6*d.* net.—*The Passing of the Great Race; or, the Racial Basis of European History.* By MADISON GRANT, Chairman of the New York Zoological Society. London: G. Bell and Sons. 1917. Pp. 245. 8*s.* 6*d.* net.—The study of ethnology and of comparative psychology has received an impetus from the "general post" occasioned by the state of almost universal warfare, which is not likely to diminish with the return of peace. The administration of law and order among peoples whose habits of thought and mode of life differ fundamentally from our own requires a sympathetic insight into motives only to be attained by careful study of the past and the present. In Mr. Perry's book, one of the ethnological series of publications issued by the University of Manchester, an inquiry is made into the effects produced by the stone-using immigrants upon the less-advanced inhabitants of Indonesia—a term here used to include not only the East Indian Archipelago, but also Assam, Burmah, the Malay Peninsula, the Philippine Islands, and Formosa. These immigrants are credited with the introduction of terraced irrigation, of metal-working, and of rice-growing, as well as the foundation of lines of chiefs and of a warrior class. The author's investigations are part of a wider inquiry to be extended to other regions of the earth embracing the whole development of civilisation.—Mr. Grant's book deals with the racial history of Europe and examines the physical and psychological characteristics of its races rather than the domains of nationality and language. Racial traits dating back to the time of tribal man anterior to civilisation are discussed in relation to their influence on the present-day inhabitants. His statements are often piquant and likely to provoke discussion. A typical sentence runs: "We Americans must realise that the altruistic ideals which have controlled our social development during the past century and the maudlin sentimentalism that has made America 'an asylum for the oppressed' are sweeping the nation towards a racial abyss."

The Passing On of Life: a Talk about Ourselves. By Viscountess FALMOUTH. London: George Routledge and Sons, Ltd. 1918. 2*d.*—This is a tract on the reproduction of the human species, and is intended to prepare the minds of juvenile readers for the absorption of requisite knowledge on this subject. It is founded on the axiom that "Right Thinking Leads to Right Doing." The contemplation of flowers and butterflies and birds leads up the staircase of life to man, and the passing on of human life, when controlled by moral standards, is regarded as the highest function of the body. The first edition of this useful pamphlet was reviewed in our columns on Jan. 6th, 1917.

The Lau Islands (Fiji) and their Fairy Tales and Folklore. By T. R. ST. JOHNSTON, F.R.G.S., F.Z.S. London: The Times Book Club. Pp. 145. 5*s.* net.—Mr. T. R. St. Johnston, whose entire familiarity with the island groups of the Pacific is shown in every line of his writings, prefaces his book with a note from "Somewhere in France," for he is serving at the moment as a temporary Major in the Royal Army Medical Corps. The Lau Islands lie about midway between Fiji and Tonga, some 200 miles from either group, and the author discusses their importance from three separate points of view: utilitarian, as a valuable asset to the copra industry of Fiji; political, because of their geographical and historical relations with Fiji; and scientific, in offering abundant material for a study in comparative ethnology. It is to illustrate the third point that his recapitulation of the fairy tales of the Lau Islands and their folklore is mainly directed, but reference is made to Mr. Basil Thomson's well-known book, "The Fijians," which contains a concrete study of the customs of the natives. Mr. St. Johnston has limited himself, therefore, to legendary folklore and to the doings of the people of the Lau Islands, "whom I know best." How well he knows them can be judged by such chapters as the second one on South Sea Magic, the fourth, entitled "The Duel 'tween God and Ghost," his summary of the legends of the Exploring Islands, and his account of the "Shark God" and the Father of Serpents.

New Inventions.

A NEW EYE SPUD.

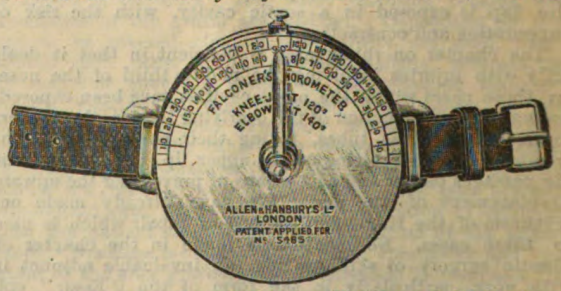
THOSE practitioners who receive many patients suffering by reason of the ingress of foreign bodies to the surface of the eye must have been struck with the inadequacy of the instruments in use for the removal of these foreign bodies, particularly of those which adhere to the surface of the cornea. There is but one instrument, the spud, a sort of maid-of-all-work, useful but lacking refinement and distinction. The spud of usual pattern is merely a narrow strip of metal thinned to a blunt edge, and since it is essentially a digging tool it is not good for the removal of the foreign body which is just stuck on to the surface of the cornea. The most dextrous use of the ordinary spud can scarcely avoid a corneal abrasion. For the removal of the ordinary superficial foreign body I have designed a spud (see Figure) calculated to "lift" the foreign body from the eye. On the usual metal handle is mounted a steel stem, this terminates in a small angled piece of steel. This end-piece is shaped like a plano-convex lens, it measures a couple of millimetres in diameter, is set at an angle of 45° to the line of the stem, and the surfaces are placed so that the plane looks towards the handle and the convexity away from it. The edge of the steel end-piece is ground as finely as the shape allows; it is so sharp that when pushed forwards on the hard surface of the finger-nail it will remove a fine shaving of horn. For the removal of a foreign body from the surface of the cornea the eye is anæsthetised in the usual way, the lids are held apart, and the globe is fixed with the finger-tips of one hand. Then the new spud is directed to the eye vertically to the corneal surface with the edge of the end-piece as close to the foreign body as possible, gentle pressure of the spud on the cornea will cause the convexity of the end-piece to depress the corneal epithelium below it, so that a gutter is formed beside the foreign body and the edge of the instrument lowered in relation to the foreign body. A forward movement of the instrument from this position will lift off the foreign body cleanly and without abrading the epithelium. This new spud is not a maid-of-all-work. It is not intended to be used for digging out foreign bodies. To use it for such a purpose is to ensure disappointment. It is a spud of the "first instance." It will lift off the new placed invader more neatly and expeditiously than any other form of spud.

The new instrument is made by Messrs. John Weiss and Son, 287, Oxford-street, London, W. 1.

Harley-street, W. N. BISHOP HARMAN, F.R.C.S.

AN "ARTHROMETER."

THE illustration depicts a new device for measuring the angles of movements of joints, which has been designed by Mr. Wilbraham Falconer, Superintendent of Mechanical Treatment in the Red Cross Clinic for the physical treatment of disabled officers. This "arthrometer" is simple in construction and easily adjusted to the limbs, and the



measurements are quickly taken. It is intended to be used with all joints and therein differs from the various forms of protractors and goniometers at present in use. If properly adjusted to the limb, the readings cannot be otherwise than accurate. It is manufactured by Messrs. Allen and Hanburys, Limited, 48, Wigmore-street, London, W. 1.

Devonshire-place, W. R. FORTESCUE FOX, M.D. Lond.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 9, 1918.

Phthisis in Factory and Workshop: The Ministry of Health Bill.

IN another column of this issue of THE LANCET we publish a striking article by Professor BENJAMIN MOORE on the conditions leading up to, or accompanying, the incidence of pulmonary phthisis in workshops and factories. The article is founded upon information which Professor MOORE has personally gathered, and in it he sets forth powerful arguments for the institution of an industrial health service. For the author has for some time been engaged in studying how far the rate of incidence of phthisis in different sections of the community varies with the strain of the conditions, with the hours of employment, and with the nature of the work. Observation during prolonged visits to workshops, statistical study of the operations of the National Health Insurance Act, and investigation of the returns of the Registrar-General, have been carried out and the results collated in the paper to illustrate the effects of urban types of employment in influencing the prevalence of phthisis.

We know that pulmonary phthisis actually kills more males than females, but Professor MOORE states—what many have not realised—that this greater death-rate among males applies only to the urban conditions of life, and is due to the modern conditions of factory and workshop life. The reverse holds good for the rural dwellers, in whom the death-rate among females remains higher than that of males in every age-group. In both town and country nearly twice as many girls as boys die of phthisis between the ages of 10 and 15. The important point is, that while until the twentieth year the mortality in both sexes from pulmonary phthisis is greater in rural districts than in urban districts, between the twentieth and thirtieth years the conditions in the towns become reversed. After the thirtieth year the disease preponderates greatly amongst urban males as compared with urban females; but no such disparity is observable between the death-rates of rural males and rural females, and in the towns the disparity is a recent occurrence not to be observed in the returns of 70 years ago. Professor MOORE'S statements are well supported by four charts selected to illustrate the contrasts in death-rate from pulmonary phthisis in accordance with occurrence in urban or rural conditions. The four charts are plotted to the same scale. The first compares rural areas with urban areas; the second shows the London area, where the curves well display the marked difference between the mortality of males and females; the third contrasts Lancashire and Westmorland; and the fourth Warwickshire and Dorset. It emerges from these charts as a general rule that in typical rural districts death-rates of males and females lie close together, whilst in urban districts the male death-rate is vastly the higher during the middle period of life. Professor MOORE'S reasons for the curves of the charts are so clearly set down that they require no analysis or simplification from us. We may add that he seems to us to be generally convincing, though the remarks on the printing trade are capable of misinterpretation. It is incorrect to say that machine managers are better organised than printers' assistants, although, as highly skilled men, they naturally earn more money per hour than their assistants. Secondly, Professor MOORE speaks of composing frames being set back to back, "so that the consumptive printer can spray the man working opposite to him and facing him at a distance of only two or three feet." But the workers at the frames cannot be less than five feet apart, while the upper cases are usually on a level with the man's eyes, standing erect, and the work is done with the head bent downwards.

We regard Professor MOORE'S paper, though dealing with only one disease and one section of the population, as very illustrative of the kind of work which has to be done in the near future, and for the proper doing of which a Ministry of Health is rightly demanded, so that widespread conditions of ill-health can be treated on some general plan by a central authority. It is being largely guessed that the recent changes at the Local Government Board have arisen from the desire to end a period of delay in the appearance of the Bill setting up this Ministry. The guess is as true as such general impressions frequently are, and the actual first reading of the Ministry of Health Bill will almost synchronise with the promotion of Mr. HAYES FISHER to a peerage and the appointment of Sir AUCKLAND GEDDES as President of the Local Government Board, retaining office also as Minister of National Service. The delay in the Bill has been unfortunate, although circumstances, we admit, have made the course of the Government very hard when so large a measure was in contemplation. The Bill to be introduced by Dr. ADDISON under the ten minutes' rule will set up two separate departments, one for England and Wales, and one for Scotland.

The Contributions to Red Cross.

BY a special effort recently made upon a day set aside for the purpose, and advertised throughout the country as "Our Day," a large sum of money, or what would once have seemed a large sum of money for such uses, was raised by the British Red Cross. Under the stimulus of such effort and advertisement many gave to the full extent of their power, and, so it is hoped, many contributions were won to this great cause which otherwise would have remained ungiven. It is well, however, that all should realise without distinc-

tion of class, and whether able to give little or much in comparison with their neighbours, that the claims of the Red Cross are not to be satisfied with a donation which may be substantial enough from the giver's point of view, or with a generosity which is only evoked by the appeal of a particular canvasser, or social occasion. The work of the Red Cross Society, in the performance of which thousands of men and women have toiled ceaselessly since the early days of August, 1914, is neither over nor nearly over.

The end is not even in sight, although the cessation of hostilities on all fronts may seem to be a matter of a few weeks, and although in the Eastern and Southern areas of war fighting has ceased with almost bewildering suddenness. This merely means that so far as Red Cross work is concerned the provision of material in certain directions will not have to be made with a view to future battles, and that the number of wounded men so far as those areas are concerned has become, or will be shortly, a matter of certainty and not of calculation or speculation. The cessation of hostilities has been achieved only in a limited portion of the field of war, whereas in others, on land and sea, bloody battles may yet precede the armistice, which we confidently expect will be the forerunner of final and lasting peace. No armistice, however, will bring to a conclusion the sufferings of the wounded which it finds lying on the field of battle or in the hospitals at home and abroad for which the Red Cross Society is responsible. The work remaining before the Society may diminish in volume by degrees, but the subscriptions which are necessary if its efficiency is to be maintained must be kept up to the end. The "clearing-up" processes will severely tax the energies and resources of the United Kingdom—and indeed of the whole world—and the organisation which we associate primarily with active warfare and its immediate results will be working at full speed when other energies are being discontinued. Wounded and sick men will remain dependent upon surgical and medical aid to restore them to comparative strength and well-being not for weeks or months but for years, and so far as the Red Cross Society may be responsible for their treatment, so long must its claims be a first call upon the generosity of all in the country.

The voluntary system, the custom of appealing to the liberality of individuals to supplement or to take the place of the efforts of the State where physical suffering or destitution is concerned, has given us the great hospitals and other charitable institutions of which the country has ever been justly proud, and it has given us the Red Cross Society. We need not dwell upon its previous achievements in our own recent war in South Africa or in succouring the wounded in the wars of foreign nations. At the beginning of the present terrific struggle it was soon realised that the military authorities had their hands too full of other matters to be able to undertake the care of the wounded without most strenuous assistance from everyone who might be able to help with hand, brain, or purse. That need for the coöperation of all has continued and will endure long after the last shot has been fired and the last wounded man has been borne to the dressing station, and that need we urge upon the public. When the immediate danger seems to have passed away for ever, let us not forget the seamen and soldiers who struck the last blows that repelled it.

Anoxæmia.

THE needs of the flying man and of the poison-gassed soldier have perforce stimulated the study of the physics of the circulation. The airman, whose lungs are sound, goes up into regions where the oxygen in the air is insufficient for his needs. The gassed soldier has his respiratory area so diminished that he does not obtain enough oxygen from the ordinary atmosphere. Both suffer from anoxæmia and require an addition of oxygen to the air which they breathe, on a scale which could not conceivably be supplied by the wasteful methods in vogue before the war. No. 10 of the reports of the Chemical Warfare Medical Committee, just issued by the Medical Research Committee, deals with the administration of oxygen in irritant gas poisoning and gives an admirable summary of the indications and methods. In acute poisoning by lung-irritant gases the danger to life, so far as present knowledge goes, is mainly due to interference with the oxygen-supply to the tissues. It is very important to understand how the imperfect oxygenation is produced and how oxygen administration prevents it. The ordinary types of irritant gas produce, after an interval of some hours, a condition in which the alveolar tissues become swollen and liquid exudes into the alveoli, with the result that the absorption of oxygen occurs much less readily than under normal circumstances. By adding oxygen to the air breathed we can easily increase by several times the diffusion pressure, which drives oxygen through the water-logged layer into the blood. The immediate improvement in colour, pulse-rate, and general condition testifies to the remedial effect of the inhalation. So far the matter is simple. But recent investigations at the Canadian Hospital at Taplow show that other factors have to be considered. It has been proved that deficient oxygenation of the blood may be due to imperfect ventilation of a part only of the lungs. HILL and TWORT, as well as ZUNTZ, came to the conclusion that perfectly healthy persons may exhibit some degree of anoxæmia during quiet breathing; and rapid and comparatively shallow breathing is frequently seen in the acute stages of irritant gas poisoning. Experience at Taplow has shown that the tendency to uneven distribution of air, with its consequent anoxæmia, is greatly increased in the recumbent position. There is, too, a large variation in the individual response of the respiratory centre to anoxæmia. In some Cheyne-Stokes breathing is produced with the greatest ease; in others consciousness is lost before the regulative machinery comes into action. The nervous regulation of breathing and the function of the bronchial muscular layer are factors as yet imponderable, for clinical evidence is still imperfect owing to the failure on the part of clinicians to recognise the early symptoms of anoxæmia or to realise its clinical significance. These deficiencies are now likely to be made up by the controlled administration of oxygen which the Haldane apparatus has made possible.

THE next session of the General Council of Medical Education and Registration will commence at 2 P.M. on Tuesday, Nov. 26th, Sir Donald MacAlister presiding.

Dr. H. H. Tooth, after four years of continued service with the Forces, two years of which have been spent abroad, has returned to his hospital duties and civilian practice.

Annotations.

"Ne quid nimis."

THE QUATERCENTENARY OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

IN view of the urgent claims of the present no concerted action has been taken by the Fellows of the Royal College of Physicians of London to celebrate the 400 years which have elapsed since Thomas Linacre founded the College in the year 1518. But at the conclusion of the Harveian oration, which we have printed in full, the President, Dr. Norman Moore, after congratulating the orator, gave a brief and learned address befitting the occasion. He recalled the early circumstances of the College and the names of the first six Fellows, handing over to the College Library as a gift from himself a book which belonged to John Chambre, the first Fellow named in the Charter, and physician to Henry VII. and VIII. This done, he received at the hands of Major Michael Foster a Latin letter (the text of which, as well as the official answer of the College, we print elsewhere) from 16 Fellows now serving with the Armies in France, extolling their College and recording "the new regiment of fevers which has descended upon the earth, as though set free from Pandora's box." The letter ends, as is traditional in the College, with a Greek message: "Rejoice; we win," to which Dr. Moore made the felicitous reply: "We do rejoice; let right prevail." The messenger was rewarded by the President with a denarius of Caligula, whose tower still remains in part at Boulogne, and a drachma struck at the place where Hippocrates practised medicine. At the conclusion of this ceremony the President handed the Moxon medal of the College to Dr. F. W. Mott.

THE INCUBATION PERIOD OF INFLUENZA.

THE incubation period of influenza is variously given in the text-books as from a few hours to four days, most frequently three to four days. The communication which we published last week by Major Michael Foster and Major H. Anstey Cookson on a small, localised epidemic is of interest in that the circumstances under which the first case of influenza was admitted into a surgical ward were such as to enable observations to be made upon the incubation period almost under the conditions of an exact experiment. Owing to the lack of beds in the medical wards a man suffering from an attack which clinically was of the nature of influenza was admitted into a surgical ward in which no case of medical illness had occurred for some days. Eight cases subsequently occurred in this ward, six of them in the beds immediately in the neighbourhood of the first patient and two on the opposite side of the ward. It seems possible that one of the latter cases may have been a fresh case introduced into the ward, though he may have been infected from the original patient. Although the nine cases showed somewhat different manifestations, there can be little doubt that they were all of an influenzal nature, and the diagnosis was established bacteriologically in two of them. The analysis of the onset of the cases with the aid of the diagram given in the paper seems to justify the conclusion arrived at by the authors—namely, that in all these cases the incubation period was about 48 hours, and that where the possibilities of accurate observation were greatest the incubation period approximated most closely to a 48-hour period. On the assumption that the cases were spread from bed to bed, and not all directly from the first patient, an assumption which seems reasonable to us, Major Foster and Major Cookson conclude that infection occurs only within a narrow radius of the patient. Their paper is a valuable piece of clinical research.

HEALTH AND EDUCATION.

THE state of the Holborn streets in early October, owing to neglect following a strike, may have recalled to the older inhabitants of London the condition of many thoroughfares 40 or 50 years ago, but it is only when contemplation is carried back to the condition of things in the early part of last century that there is realised the wonderful progress made in sanitation and public health since that time. Great, however, as this progress has been, it might have been still greater if the public had been more alive to the need for practically applying the knowledge which science has placed at their disposal. Ignorance rather than callousness has retarded the wider application of sanitary knowledge as that knowledge accumulated; the ignorance remains, and if public apathy could be overcome it would be difficult to place a limit on the benefit to life and health which would thereby result. After the war it will be necessary that everything possible should be done to conserve the health of the people, but the best results can only be obtained if the people themselves intelligently coöperate in the efforts made towards this end, and for this it is necessary that they should understand the broad principles on which public health legislation is founded. On a small scale the experience of various local centres and institutions has shown the educative value of simple charts and diagrams illustrating the dangers to life and health which surround us and the means by which they may be avoided; while the exhibits intended for popular education shown in the entrance hall of the South Kensington Natural History Museum admirably illustrate how important scientific facts may be imparted to the people in simple and comprehensible guise. There is no doubt that a public health exhibition under Government ægis illustrating the various ways in which science has been brought to bear on sanitation and public health, and embracing, as did the Health Exhibition held at South Kensington in 1884, health, food, dress, housing, and education, would result in a greater stimulus to the study of health matters on the part of the public. A real advance in public health knowledge, and a consequent wider interest in the legislation necessary for carrying out promptly and effectively pressing reforms, are the urgent needs of the immediate future. Such an exhibition as we have in mind, if international in scope, would have effects of incalculable range; for the Allies, who have been fighting side by side in the cause of established civilisation, as well as neutral countries, would be brought into close touch by the common object of placing that civilisation on the surest basis of prosperity—a firmly consolidated international health. For these reasons the holding of another exhibition on the lines of that held at South Kensington in the early "eighties," and popularly known as the "Healtheries," deserves the earnest consideration of the Government.

AN UNUSUAL TYPE OF EMPYEMA.

SOMETHING approaching almost an epidemic of empyema associated with pneumonia occurred in the area dealt with by the base hospital at Camp Upton, New York, during last winter and spring. The clinical characters of these cases indicated that they were of an altogether different type from that with which we are accustomed, whilst operative procedure upon them was attended by an unusually severe mortality. Obviously such cases demanded careful clinical study, and an admirable account of this condition is given by Major Harlow Brooks and Major Russell L. Cecil in the *Archives of Internal Medicine* (September, 1918). Eighty cases form the basis of this study. In most instances it was discovered that the causative agent, not only of the empyema but also of the pneumonia associated with it, was the so-called *Streptococcus hæmolyticus*. In this series of cases cultures were made from the sputum and the pleural exudate. The following résumé of the results obtained is given:—

1.	Pneumococcus in sputum and exudate ...	15 cases
2.	Streptococcus ,, ,, ,, ,, ...	40 ,,
3.	Mixed infections	10 ,,
4.	Sterile empyemas	15 ,,

The pneumococcal empyemas differed in no respect from those seen in civil practice. The streptococcal empyemas made up 49 cases: 9 were instances of a streptococcal pleural infection associated with a pneumococcal pneumonia, 5 were infections by *Streptococcus viridans*, which differed in no marked manner from the *Streptococcus hæmolyticus* cases.

The patient usually complains of cough, fever, and pain in the side. The onset is usually gradual. Sputum is scanty and viscid, rarely rusty. Fever runs an irregular course. The physical signs before the onset of empyema are often indefinite. The empyema itself develops surprisingly early, a positive diagnosis being possible in, on an average, 5·4 days after admission to hospital. Often it develops before a conclusive diagnosis of pneumonia can be made; these empyemas are, in fact, imposed on, and do not merely succeed, the active stages of pneumonia. A most constant and suggestive clinical sign is profuse sweating and marked exhaustion. Abdominal rigidity is strikingly absent. Skin tenderness (not hyperæsthesia) over the involved area is frequent and has, in part, aided the selection of a point for aspiration. Physical signs have been disappointing; even X rays cannot be absolutely depended upon. Percussion is of most value. It is curious to note that pneumothorax developed in six instances, due, it is suggested, to the rupture of minute pulmonary abscesses. The fluid removed by the needle is light yellow and cloudy; later in the disease it becomes purulent.

Though all the cases of empyema were associated with pneumonia, in many the pneumonic process had been very slight, and the empyema far outweighed the pneumonia in clinical importance. Most of them seem to develop from a broncho-pneumonia. The mortality in this group of 49 streptococcal empyemas is high—61 per cent. As regards treatment, whilst in the usual run of cases early operation is beneficial, in these streptococcal cases similar measures are much less effective. Early operation, in fact, seems definitely contra-indicated: "Those patients operated on early have, almost without exception, died, whilst those in whom the operation has been postponed until the pus has become thick and gelatinous ..... recovered." It is evident from this general account that a very special type of pulmonary-pleural infection has been recognised. A very similar outbreak, occurring during the last quarter of 1917 in a camp at Zachary Taylor, Kentucky, was described in THE LANCET of June 8th, 1918, where attention was also called to the high incidence of empyema at Aldershot. We think it probable that the same thing is occurring elsewhere.

WAR DAMAGE AND THE STATE.

A DEPUTATION from the Committee on War Damage was received recently by Mr. G. L. Wardle, M.P., Parliamentary Secretary to the Board of Trade, its object being to obtain compensation from the State for those who have suffered through air raids or bombardments. A memorial on the same subject presented to the Prime Minister some time ago met with a favourable reception, and the more recent deputation lost no time in making it clear that in its opinion Mr. Lloyd George had accepted the principle of national responsibility, and that the fact that no tangible result had followed upon his observations amounted to something very like breach of faith on the part of the Government. We gather from a printed report of what occurred that members of the deputation received by Mr. Wardle laid their arguments before him with some vehemence, and were not a little disappointed at finding that he could give no pledge beyond promising to acquaint the Government with their views, and asking for particulars showing the extent of the liability which they wished the Government to undertake. With some reasonableness it was pointed out to Mr. Wardle that the acceptance of the principle of State compensation for damage to person or property arising from air raids or bombardment should not be affected by an exact preliminary calculation of the sum of money involved, The cogency of some of the arguments put forward by the deputation must also be admitted, even though full weight be allowed to the obvious reply that the State provided an insurance scheme of which owners of property at any rate might have availed themselves. The points insisted upon by the deputation were, to speak generally, that the districts most affected by air raid and bombardment have been precisely those which, owing to the danger of air raids, of bombardment, and possibly of actual invasion, have been the worst sufferers financially throughout the war. This would, of course, include towns on the south-east and east coasts, whose usual visitors have filled to overflowing seaside places in the west and consequently out of the danger zone. The deputation claimed to be able to say, as representing 842 municipal authorities and a population of 32,000,000, that the country at large was willing to pay for the sufferings of those whose accident of domicile had rendered them most liable to attack. We can well believe that this is the case, and we desire to give our own support to the views expressed by the deputation and to the demand which it has laid before the Government. No doubt a vast number of owners of property insured against the risks of damage from air raids or bombardment; but universal insurance, including that of the homes of the poor and of their contents, could not reasonably have been expected, and no doubt nothing approaching universal insurance took place. Something, in short, must be allowed for the human weakness of those who are imprudent, forgetful, procrastinating, or financially unprosperous, before we consider the provision of insurance by the Government as a complete answer to any claims made upon it. Moreover, there is the question of personal injuries, and looking at the matter from the point of view of the medical profession we cannot help bringing forward such an example as this. Our readers can picture a medical man having a practice in an East Coast town, summoned from his home and possible underground shelter to attend those injured by

bombs, being himself wounded by an explosion and being informed later that his house had been bombed in his absence, his wife or members of family being also hurt. If he were found, quite imprudently we admit, to have failed to insure to the fullest extent, or to have allowed his insurance to lapse, we should certainly feel impelled to support the view, which no doubt he would hold, that the State ought at least to help him to bear his loss. It will be recognised that the case we have put forward is not wholly imaginary, and because of it, and others, we sympathise in the abstract with the views put forward by the Committee on War Damage.

EPIDEMIC POLIOMYELITIS.

IN this country, happily, we have had so far no severe or widespread epidemics of acute poliomyelitis, such, for example, as that which swept over the State of New York two years ago, and which, in a population of about 10½ millions, attacked no fewer than 13,164 persons, most of them under 5 years of age, of whom 3331, or about 25 per cent., died; and among those who recovered a considerable proportion were left paralysed for life. In England the manifestations of the disease, while not uncommon, have hitherto been on a comparatively small scale. The total number of cases notified in 1917 was 357, distributed widely over the country in small groups of cases. The largest outbreaks in recent years occurred in Devon and Cornwall in 1911, and were carefully investigated on behalf of the Local Government Board by Dr. R. J. Reece.[1] Three localised outbreaks of epidemic poliomyelitis reported to the Board during 1917 were made the subject of special inquiry by medical inspectors. The three reports have now been issued together, along with a prefatory note by Dr. R. J. Reece, Assistant Medical Officer to the Board.[2] The first report is by Dr. A. S. MacNalty and deals with an outbreak, comprising 42 cases and 3 deaths, in the Esher and the Dittons urban district and in the adjoining Epsom rural district, 33 attacks being referred to the former and 9 to the latter. Twenty of the cases suffered from definite paralysis, in 12 of whom, when last seen, the paralysis still persisted. The spread of the disease generally was from person to person. Dr. MacNalty in his report gives a diagram representing graphically the spread of the infection and the grouping of the cases. Mild or so-called "abortive" cases occurred side by side with paralytic cases in the same households; such mild cases when unrecognised probably played a not inconsiderable part in diffusing the infection. The first attacks were reported in mid-July and the outbreak lasted until the end of August. The second report is by Dr. H. A. Macewen and relates to the occurrence of 11 cases of acute poliomyelitis in the borough of Cambridge and in its vicinity during the autumn of 1917. In this instance also the malady appears to have been spread by personal infection. The origin of this local outbreak was difficult to trace, and no connexion between it and a previous occurrence of the disease could be discovered. There was only 1 death among the 11 cases. The third report is by Dr. J. P. Chandler, and is concerned with an investigation of three cases of acute anterior poliomyelitis which occurred among the boys at Cheltenham College during the month of October, 1917. The precise source of the infection was not definitely determined, but it is thought very probable that it was brought to the college by a returning schoolboy at the conclusion of the summer vacation. The first of the cases had a fatal termination, but the other two recovered. There were ten notifications of poliomyelitis in Cheltenham town during 1916, but apparently no connexion existed between these cases and those at the college in 1917. The publication of these three reports serves, among other things, the useful purpose of reminding medical men that poliomyelitis is liable to occur, sporadically or otherwise, in any part of the country, and that practitioners should be on their guard against overlooking mild, abortive, or anomalous cases which, if not properly dealt with at once, might diffuse the infection in the locality and give rise to a serious epidemic. Epidemic poliomyelitis is, as our readers are aware, one of the saddest of diseases, since the tender-aged victims who survive the attack are often left permanently crippled or deformed.

ULSTER AND THE MEDICAL NEEDS OF THE ARMY.

AT the first meeting of the Ulster Medical Society for the session 1918–19, held in the Belfast Medical Institute, when Dr. W. Donnan, as retiring President, introduced his successor, Dr. J. Colville, Dr. F. Goodbody made a strong appeal for doctors for the front owing to the great necessity for them during the present Allied offensive. The medical profession in Ireland is being strongly pressed for fully qualified practitioners with the Army, and the Queen's University of Belfast has definitely decided to hold a special medical degree examination at the end of November, so that there shall be no delay until the usual degree examinations in March of next year. But they have made certain clear conditions:—

1. Every candidate before being admitted must sign a document that in the case of men they will go to the front, and in the case of women that they will place their services at the disposal of the War Office.

2. Those candidates who pass must provide evidence before their degrees are conferred that they have "signed on" with the War Office, otherwise their degrees will be forfeited.

"The possibility of getting young medical men in Ireland has been rendered doubtful," says our Belfast correspondent, "because there is no guarantee that if a young doctor throws up his practice and goes to the front he will not on his return find his patients in the hands of others who will not be very keen to give them back." Our correspondent proceeds:

"The bureaucratic authorities in charge of the petrol-supply are cutting down the amounts of spirit to doctors, with the natural result that, in addition to the amounts being smaller and often much poorer, the mileage of the cars is being diminished. The consultants and those attending the military in hospitals and camps are finding that it is impossible to get through work with the diminished supply of such frequently poor petrol; while older men—who would be willing to do the extra work of younger doctors, so as to let the latter off to the Navy and Army—realise they could not, with their present petrol-supply, do the work. What makes it specially aggravating is that every day civil officers are using petrol, and ambulances are seen running about with, at times, some vegetables or clothes (washed or soiled), as the case might be, from one military hospital to another. The whole train service is so greatly restricted that it is of little use to doctors. Owing to the inadequate supply of doctors the Dublin corporation has demanded the release of several medical men who have been deported and interned."

TUBERCULOSIS IN FRANCE.

The Return of the Tuberculous Interné.

CIVILIAN prisoners are being repatriated from Germany through Switzerland in increasing numbers. One of our French correspondents writes that something like 1000–1300 are arriving daily at Evian, and of these about 1 per cent. are found to be tuberculous, their condition being a product of the insufficient food, defective hygiene, and harsh circumstances of captivity. To ensure sufficient and immediate care for these unfortunates the Minister of the Interior has set up machinery at Evian for weeding out the tuberculous patients on their arrival, with a view to classification and treatment appropriate to each several case. A rapid separation into three categories is made: (1) the grave forms, which are sent to special hospitals; (2) the suspects, who are reserved for careful examination; (3) those found unaffected, who are then allowed to continue their journey. The hospital of suspects includes 180 beds, and to it is attached a hostel for healthy children, where sufficient isolation is obtained without complete separation from their possibly infective parents. At the end of 10 days' observation the patient then recognised as non-tuberculous is allowed to proceed. Those found to be tuberculous are classified as follows: (1) advanced or rapid lesions, needing rest in bed; (2) old cicatrised lesions with good general condition; (3) cases presenting some active symptoms, but whose lesions are slight and closed; (4) cases with open lesions and therefore infective, but with a prospect of cure.

The men are generally alone, the women more often accompanied by children whose health is not always the same as that of the mother, who does not wish to be separated from them. Four possibilities have to be considered: (*a*) infective mother with infective child; (*b*) infective mother with non-infective child; (*c*) non-infective mother with non-infective child; (*d*) non-infective mother with infective child; the last a very rare category. Among the non-infective children it is necessary to define: (1) the healthy; (2) the anæmic, debilitated, and the subjects of tuberculous glands; (3) those with tubercle of bone or joint. To meet the needs of these various classes there has been established a hospital of 56 beds in the neighbourhood for grave cases, men and women, their children being placed in a neighbouring hostel. Curable tuberculous cases are sent into other establishments, the men to sanitary stations in the interior, where they join the discharged soldiers. Several establishments for women are available according to the gravity of their case. At the village of Monnetier-Mornex a hospital of 125 beds has been set up at 800 metres above sea-level, a house of 30 beds for infective women, a hostel with 45 beds for healthy children, and a house of 30 beds for infective children. The Hospital of Ste. Eugénie, near Lyons, with 140 beds set up by the American Red Cross, also receives tuberculous women. Children with tubercle of bone or glands are sent to marine hospitals. Finally, the departmental committees of assistance for the military cases of tubercle are setting their vast organisation of regional sanatoriums at the disposal of the returned civilian.

Propaganda Work in France.

At the recent annual meeting of the National Association for the Prevention of Consumption, held in London, an informing address was given by Professor Selskar M. Gunn, Associate Director of the Commission for the Prevention of Tuberculosis in France. His main theme was the need for popular education in tuberculosis, as illustrated by the work of the Commission in France. "No matter how thorough is the medical care of the population," Professor Gunn said, "provision for the sick and a campaign against tuberculosis cannot secure complete results until each individual has been taught the fundamental facts of correct and healthy living and follows the teachings. In the last analysis the prevention and the eventual elimination of tuberculosis are a matter of sane living, of following the most simple physiological laws of health, good food, adequate rest, proper exercise, and fresh air. At present these facts are the property of a limited number of persons in the community. It is essential, if tuberculosis is to be conquered, that the scientific knowledge of the few be given to all. Professor Gunn then described the adaptation of some of the plans found useful in the United States to the conditions in France. Five different methods have been employed: newspapers, exhibits, posters, pamphlets, and public meetings. 1. A series of articles prepared by the educational division of the Commission have been printed in 36 newspapers, explaining the origin of tuberculosis, the ways in which it can be cured, and the French newspapers are rapidly coming to realise their great opportunity of public health education. 2. The travelling exhibit emphasises the main facts about tuberculosis by means of wall charts. There are also models of a dispensary, an out-of-doors sleeping-porch, and a kinema with films. The exhibit, which is carried on a truck from town to town, is in charge of a directress and has a personnel of chauffeur, moving picture operator, two lecturers, and an advance agent. There are now three such exhibits in operation and within a few months the number will be increased to six. They have already traversed the departments of Eure-et-Loir, Loir-et-Cher, Indre-et-Loire, Cher, Allier, Ille-et-Vilaine, Finistère, Cotes-du-Nord et Loire-Inférieure. 3. Conferences preceding the exhibition have been held in communities of 3000 or more persons, the audiences in many instances numbering 50 per cent. of the population. Special sessions have been arranged for school children, who attend with their teachers, as well as conferences for mothers and meetings in factories. 4. Moving pictures on health subjects form an important part of the programme. Some of the films are scientific presentations of disease; others are animated cartoons on health. The meetings are thoroughly advertised; many posters are put on the walls and the local newspapers carry notices. 5. The Commission has prepared a large variety of brochures in order that the people attending its meetings may have something to take home and study at leisure. The booklets are illustrated by French artists, and a million and a half copies have already been distributed."

Professor Gunn has found that the French people are glad to know the facts about tuberculosis, and he has had the hearty help and coöperation of the préfets and maires, many of whom have acted as chairmen at the meetings arranged by the Commission.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

Meeting of Comitia.

AN ordinary Comitia of the Royal College of Physicians of London was held on Oct. 31st, Dr. NORMAN MOORE, the President, occupying the chair.

The following candidates having passed the required examination were admitted as Members of the College: Dr. J. C. Matthews, Dr. S. A. Moore, and Mr. H. J. Orr-Ewing.

Licences to practise physic were granted to 93 candidates who had conformed to the by-laws and regulations and had passed the required examinations.

Certain College officers and examiners gave their faith to the College.

The following communications were received:—

1. The Secretary of the Royal College of Surgeons, dated July 26th and Oct. 11th, reporting proceedings of the Council of that College on July 25th and Oct. 10th respectively.

Note.—A supplementary letter states that at the meeting of the Council on July 25th it was decided—

(*a*) "To omit the names of universities in Germany and Austria-Hungary from the list of hospitals and schools of medicine and surgery published in the College Calendar as the places from which certificates of the professional education of candidates for the Membership and Fellowship will be received by the College for the year commencing the 1st of August, 1918."

(*b*) "That the desirability of also omitting these universities from the published list of the Conjoint Examining Board should be brought under the consideration of the Committee of Management."

This was referred to the Committee of Management.

2. Dr. Guy Wood, dated Oct. 7th, asking that the Membership, which he resigned in 1900, may now be restored to him.—This was agreed to for the first time, on the proposition of the SENIOR CENSOR.

The SENIOR CENSOR proposed, and it was resolved, that the Licence of the College which was withdrawn from Mr. William Dutton Akers in January, 1912, be now restored to him.

A Latin letter was received from the Fellows of the College serving with the Army in France on the occasion of the quater-centenary of the College, as follows:—

EPISTOLA

a dilectissimis Sociis nostris in Gallia bellum gerentibus accepta.

χαίρομεν. Τὸ εὖ νικῶτω.

Collegio Regali Medicorum Londinensium quartum saeculum vitae suae feliciter conditum celebranti et quintum jam faustis auspiciis ineunti salutem plurimam dicunt et libentissime gratulantur Socii subsignati, Gesoriaci Bononiensium inter arma collocati. Longum est nomina percurrere tot virorum illustrium qui sine ulla intercapedine continenter honorem Collegii nostri sustulerunt, scientia artem medicinae altius provexerunt, feliciter hominum corpora morbis oppressa ad integram valetudinem revocare docuerunt. Sed quotum quidque invenimus Collegium cujus alumni literas quoque humaniores urbanitate tanta et lepore ornaverint, scientiam omnis generis tutius ingenio aedificaverint, rei publicae insignius profuerint?

Quarto jam anno belli consensu omnium furore teutonico incepti peracto, militantes videmus eheu! qualis nova febrium terris incubuerit cohors, velut e Pandorae pyxide liberata, quot morbos pediculi necnon muscae, quot vapores noxii attulerint, quanta denique strage nostrorum et totius gentis humanae hostis barbarus Marte illacrimabili maxime abusus sit debellandus. Sed sortes jamdudum faustae, florent arma amplusque florebunt, praevalebit tandem justitia. Quin etiam (cum licet denique) Pheidippidis verbis sine superbia usi, spe victoriae certa Collegium nostrum valedicentes jubemus *χαίρετε νικῶμεν.*

Gesoriaci Bononiensium, A.D. ix. Kal. Oct., MDCDXVIII.

W. P. HERRINGHAM, Major-General.	W. P. S. BRANSON, Major.	CHARLES J. MARTIN, Lieut.-Colonel.
W. PASTEUR, Colonel.	GORDON HOLMES, Lieut.-Colonel.	W. E. HUME, Colonel.
JOHN ROSE BRADFORD, Major-General.	T. R ELLIOTT, Colonel	HENRY MACCORMAC, Lieut.-Colonel.
J. HUGH THURSFIELD, Major.	MICHAEL FOSTER, Major.	A. M. H. GRAY, Lieut.-Colonel.
J. A. NIXON, Colonel.	CHARLES MILLER, Colonel.	S. W. CURL, Captain.
A. J. JEX-BLAKE, Major.		

The following answer was addressed to the Fellows of the College serving abroad:—

Accepimus, O Socii, litteras vestras jucundissimas, pro quibus libenter gratias agimus. Quod si graves Reipublicae vices, si clades nostrorum lacrimabilis, publicas nobis ferias interdicunt, si etiam convivia Moderator, ut ita dicamus, Cibarius denegat, licet tamen vobiscum paululum gaudere, licet Collegium nostrum, per quarta saecula traditum, mirari. Illud vero ex litteris vestris cognitum praecipue laudamus, quod vobis inter arma inter labores inter pericula collocatis non deest tamen erga Collegium pietas, neque litterarum humaniorum cultus. Adsit utinam fausta illa dies, quum ad patriam ad domos ad Collegium redeuntes pacem cum honore referetis. Valete!

Apud. Lond. Prid. Kal. Nov., MCMXVIII.

A committee was appointed to draw up a pronouncement on the subject of influenza, consisting of Dr. F. W. Andrewes, Sir Humphry D. Rolleston, Dr. H. R. Crawford, Sir John Broadbent, and Dr. H. French.

The resignation by Sir Frederick Taylor of the office of Representative of the College upon the Senate of the University of London was accepted with great regret.

The President and Dr. Henry Head were appointed representatives upon the Conjoint Board of Scientific Societies.

The REGISTRAR proposed for the second time the following temporary by-laws:—

1. That Dr. Sydney Walter Curl, being resident abroad, be admitted to the Fellowship *in absentiâ*, any by-law to the contrary notwithstanding.
2. That Dr. Harold Benjamin Day, being resident abroad, be admitted to the Fellowship *in absentiâ*, any by-law to the contrary notwithstanding.

These were accordingly resolved.

A report was received from the Committee of Management, dated Oct. 1st, as follows:—

The committee desire to recommend that the following University be added to the list of institutions whose graduates in Medicine are admissible to the Final Examination of the Examining Board in England under the conditions of Paragraph IV., Section III., of the Regulations—viz., the Emory University of Atlanta.

The committee also report that under the provisions of Paragraph VI., Part I., of the scheme for constituting the Examining Board in England, Dr. W. Hale White and Mr. W. F. Haslam retire by rotation from the committee.

Dr. W. Hale White was reappointed a member of the Committee of Management.

After some formal business the Comitia was dissolved.

THE King has sanctioned the formation of a new branch of the League of Mercy called the Wanderers' Branch. The first President is Colonel R. J. Blackham, now D.D.M.S. of an army corps in France, and the honorary secretary is Lieutenant-Colonel E. F. Falkner. Letters may be addressed to either officer at the Army and Navy Club, Pall Mall, S.W. 1.

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND.

SUBSCRIPTIONS TO THE SECOND APPEAL.

THE following subscriptions have been received up to Monday last, Nov. 4th:—

	£	s.	d.
Sir Rickman J. Godlee..	3	3	0
North of England Branch B.M.A (per Dr. J. Don, Hon. Sec.)—			
Dr. R. S. Hubbersty...	2	2	0
Dr. J. A. Hislop... ...	1	0	0
Dr. H. Carden Pearson	1	1	0
Dr. R. A. Welsh	1	1	0
Mrs. Ethel Bowman...	0	10	0
Dr. H. B. Hunter ...	0	10	0
Dr. W. Murray	1	1	0
Drs. W. A. and E. G. D. Benson	2	2	0
Dr. D. B. Cama	1	1	0
Dr. M. Maclean	1	1	0
Dr. D. Welsh	1	1	0
Dr. J. R. Burn	2	2	0
Dr. J. Hammond ...	1	1	0
Mr. E. Spencer Evans (monthly)	0	10	0
Sir A. Pearce Gould (monthly)	5	0	0

Monthly Subscriptions.

The following monthly subscriptions have been received for October:—

	£	s.	d.
Dr. Vincent Tighe... ...	0	10	0
Dr. G. Grey Turner ...	1	1	0
Dr. W. E. Good	0	10	0
Dr. W. Luffman	0	10	0
Dr. R. Legat	0	10	6
Dr. A. E. Naish	0	10	0
Dr. J. O. Musson	0	10	0
Dr. T. W. Goodbody ...	1	0	0
Sir T. Barlow	0	10	0
Surg. P. G. S. Davis, R.N....	0	10	0
Dr. A. B. Stevens	1	0	0
Lt. J. B. C. Brockwell, R.A.M.C.	0	10	0
Major E. R. Fothergill...	0	10	0
Dr. W. S. Hart	1	0	0
Dr. A. Graham	1	1	0
Dr. Hyla Greeves	0	10	0
Dr. H. Caiger	0	10	6
Dr. K. J. Dougall	0	10	0
Dr. A. W Forrest	1	0	0
Dr. T. L. Drapes	0	10	0
Capt. H. L. P. Hulbert, R.A.M.C.	1	0	0
Dr. E. C. Morland... ...	0	10	6
Dr. H. Whitehouse ...	0	10	0
Dr. A. Hawkyard	0	10	0
Dr. W. Stewart	0	10	0

Subscriptions to the Fund should be sent to the treasurer of the Fund, Dr. H. A. Des Vœux, at 14, Buckingham Gate, London, S.W. 1, and should be made payable to the Belgian Doctors' and Pharmacists' Relief Fund, crossed Lloyds Bank, Limited.

Obituary.

JOHN WILLIAM SINCLAIR MEIKLEJOHN, M.D. EDIN., L.R.C.S. EDIN.,

DEPUTY INSPECTOR-GENERAL OF HOSPITALS AND FLEETS, R.N.

Deputy Inspector-General Meiklejohn, R.N., who died at his residence, 105, Holland-road, London, on Oct. 31st, was born at Latheron, Caithness, in 1829 and had therefore reached the ripe age of 89 years. After graduating in medicine at the University of Edinburgh in 1851 he entered the Royal Navy as assistant surgeon and was subsequently appointed to the *Illustrious*, a training ship at Portsmouth. Afterwards he became assistant surgeon to the screw steam sloop *Harrier*, which during the Crimean War took part in the operations in the Baltic. For his services Dr. Meiklejohn was awarded the Baltic medal.

In 1860 he obtained the licence of the Royal College of Surgeons of Edinburgh and became staff surgeon four years later. His subsequent service was in the Mediterranean, India, South America, and South Africa, and at various Home Stations. He was appointed fleet surgeon in 1875 and retired in October, 1884, with the rank of Deputy Inspector-General of Hospitals and Fleets.

Inspector-General Meiklejohn was a man of almost encyclopædic knowledge in many departments of natural science, especially in botany; he was a Fellow and at one time on the Council of the Linnæan Society. His extensive travels while in the Navy gave him opportunities of pursuing personal studies, but besides these interests he knew and read widely in Greek, Sanskrit, Latin, French, German, Italian, and Spanish literature and history. Architecture and archæology were other subjects he had studied closely: he was also an authority on Buddhism. For many years he was a member of the Council of the Ray Society and a Governor of the Royal Naval School at Eltham.

He married in 1875 Mary Elizabeth, daughter of Mr. William Reynolds, of Campden Hill-square, who died in 1912. By her he leaves three sons, Mr. R. S. Meiklejohn, C.B., of H.M. Treasury, Lieutenant-Colonel W. L. S. Meiklejohn, of the Indian Army, and Surgeon Lieutenant-Commander N. S. Meiklejohn, R.N.

The War.

THE CASUALTY LIST.

THE following medical officers appear among the casualties announced since our last issue :—

Killed.

Capt. F. C. Harrison, R.A.M.C., attd. Duke of Wellington's Regiment, was a student at Sheffield University and at the Royal Dental Hospital, London, and took his medical qualification in 1915, having previously qualified in dentistry in 1913. Prior to joining the R.A.M.C. he was in practice in Sheffield.

Died.

Capt. N. J. Allan, R.A.M.C., received his medical education at Liverpool University and qualified in 1916. Before joining the R.A.M.C. he held appointments at the Liverpool Royal Infirmary and at the Liverpool Maternity Hospital.

Capt. C. M. G. Campbell, R.A.M.C.

Surg. Lieut.-Com. J. Hadwen, R.N., was a student at St. Bartholomew's Hospital, and qualified in 1907. Prior to joining the Navy in 1910 he was in practice at Gloucester.

Capt. W. L. Millar, R.A.M.C., qualified at Aberdeen in 1906, and prior to joining up was in practice at Forres, where he was honorary medical officer to the Leanchoil Hospital, and was also M.O. of Kinloss parish, and medical referee for several insurance companies.

Capt. T. R. Guilfoyle, Canadian A.M.C., qualified at the Western University, London, Ontario, in 1914, and prior to joining the Canadian Contingent held an appointment at Guelph General Hospital, Guelph, Ontario.

Wounded.

Capt. H. P. Whitworth, R.A.M.C., attd. Scottish Borderers.
Major W. B. Allen, V.C., M.C., R.A.M.C.
Capt. C. F. Hacker, M.C., R.A.M.C., attached Royal Scots.
Major J. B. Scott, M.C., R.A.M.C.
Capt. C. R. Young, M.C., R.A.M.C., attached Shrops. L.I.
Capt. A. F. Argue, Canadian A.M.C.
Capt. F. B. Day, Canadian A.M.C.
Capt. H. F. Brice-Smith, M.C., R.A.M.C., attd. Yorks. L.I.
Major J. S. Levis, M.C., R.A.M.C.
Capt. F. E. Sprawson, R.A.M.C.
Capt. N. H. Little, Canadian A.M.C.
Capt. J. R. Cameron, R.A.M.C., attached Royal Irish Rifles.
Major H. B. Graham, D.S.O., M.C., R.A.M.C.
Capt. C. H. T. Ilott, R.A.M.C., attd. Royal West Surrey Regt.
Capt. R. T. Raine, M.C., R.A.M.C., attd. East Yorks Regt.
Capt. C. H. Seville, R.A.M.C.
Capt. W. B. Wilson, R.A.M.C., attached Devon Regiment.
Capt. A. R. Campbell, Canadian A.M.C.

CASUALTIES AMONG THE SONS OF MEDICAL MEN.

The following additional casualties among the sons of medical men are reported :—

Private R. H. Cuthbert, Royal Fusiliers, attached A.P.C., died in England of pneumonia, fourth son of the late Dr. W. H. Cuthbert, of Frinton, Essex.

Second Lieut. P. C. Weaver-Adams died as the result of a flying accident, younger son of Mr. E. Weaver-Adams, F.R.C.S., of Slough, Bucks.

Capt. C. A. Mallam, M.C., Royal Berkshire Regiment, died of wounds, son of the late Dr. G. B. Mallam, of South Hackney, London.

H. M. Thompson, A.I.D., died suddenly in England, second son of Surg.-Capt. M. Thompson, of Richmond, Surrey.

N. M. Haydon, O.T.C., died of pneumonia, youngest son of Dr. E. Haydon, of Newton Abbot, Devon.

Private W. H. Scott, Essex Regiment, formerly Lincs Regiment, killed in action, second son of the late Dr. I. Scott.

Lieut. C. W. Sheppard, R.E., formerly Oxford and Bucks Light Infantry, died of influenza and pneumonia, eldest son of Dr. W. J. Sheppard, of Putney, London.

Second Lieut. F. B. Bond, R.F.A., killed in action, only child of Dr. B. W. Bond, of Godalming, Surrey.

Gunner C. G. Kelly, R.F.A., killed in action, son of the late Dr. B. Kelly.

Colonel Champe C. McCulloch, jun., U.S.M.C., executive officer of the Board for Collecting and Preparing Material for a Medical and Surgical History of American Participation in the European War, has arrived in France. During his absence Lieut.-Colonel Casey A. Wood, U.S.M.C., will be in charge of this work in the Surgeon-General's office at Washington.

OBITUARY OF THE WAR.

GEORGE SELBY BROCK, M.B., CH.B. EDIN.,

CAPTAIN, INDIAN MEDICAL SERVICE.

News has been received by cable of the sudden death on Oct. 12th, from influenza, at Rawalpindi, of Captain G. Selby Brock, of the Indian Medical Service. Only son of Dr. George Brock, of Rome, he was born in the Orange Free State 32 years ago, and educated at Uppingham School and at the Universities of St. Andrews and Edinburgh, from which last he graduated in 1910, joining the Indian Medical Service in the following year. At the outbreak of the war he went to France with the first Indian contingent and served in Flanders, thus earning the 1914 Star. In the following year he returned to India to regimental duty at various stations, for the last two years at Kohat. Thence he was transferred to Rawalpindi in June of this year on his appointment as adjutant of the newly instituted "School of Instruction for Temporary I.M.S. Officers," which he had helped to organise there. Captain Brock was a fine athlete, having at Uppingham captained the School Fifteen, and while at Edinburgh won the Inter-University hurdling championship. He was also a good linguist, speaking French, German, and Italian, and shortly before his death was engaged on, and had nearly completed, the compilation of a manual on the Pushtu language and Afridi dialect. His personal qualities made him a general favourite, and his loss will be much felt, especially at the new "School of Instruction," to the success of which his attractive personality, his good influence with the young Indian officers, and his enthusiastic and excellent work were greatly contributing. He leaves a widow and two children.

GEOFFREY MOORE COWPER, M.R.C.S. ENG.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain G. M. Cowper, who died of wounds on Oct. 3rd, was educated at Darlington Grammar School and Trinity College, Cambridge, going on to St. Bartholomew's Hospital, London, where in 1914 he took the Conjoint Diploma. He joined the R.A.M.C. on the outbreak of war, and after six months of duty as anæsthetist at a base hospital in England he went to Le Tréport with a hospital unit, where, in addition to his regular duties, he had charge of surgical huts and acted also as honorary secretary and treasurer of the officers' mess. Last year he became attached, first to a West Riding regiment (Duke of Wellington's), and later to a field ambulance. Finally, just before his death, he was transferred to a Dorset regiment, and it was while working at his regimental aid-post that a direct hit by enemy artillery inflicted wounds which shortly proved fatal. Captain Cowper's superior officers write of his whole-hearted devotion to the work in hand, whether professional or recreative, which made him a true comrade, while his considerateness endeared him to the patients and nursing staff. His loss is keenly felt by all his associates.

PERCIVAL THOMAS PRIESTLEY, M.B., CH.B. BIRM.,
MAJOR, ROYAL ARMY MEDICAL CORPS.

Major P. T. Priestley, who died at Salonika on Sept. 28th, was only child of the late Rev. Thomas Priestley, vicar of Albrighton. He was educated at St. Michael's College, Tenbury, Shrewsbury School, and Birmingham University, qualifying M.B., Ch.B. in 1913, and then holding resident appointments at the Birmingham General Hospital. He joined the Birmingham University O.T.C. on its formation and received later a commission in the Special Reserve of the Royal Army Medical Corps. He was sent to France on August 14th, 1914, and a year later to the Near East, where he served at Anzac until the evacuation and then at Imbros and Alexandria. After sick leave and a period of home service, during which he had charge of Lady Tennyson's Hospital at Freshwater, he was sent in June, 1917, to Salonika, where he died of influenza after a few days' illness. Major Priestley married in January, 1916, Ellen, daughter of Charles F. Underhill, of Burton-on-Trent.

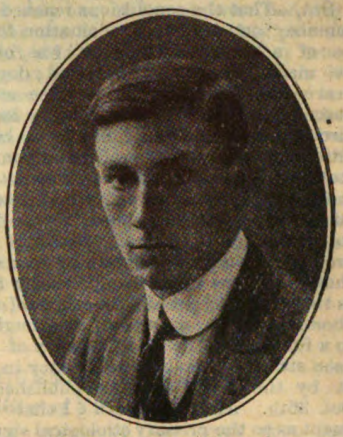
JAMES TOWERS KIRKLAND, M.B., CH.B. GLASG.,
MILITARY CROSS; CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain J. T. Kirkland, who was killed in action on Sept. 18th, at the age of 36 years, was youngest son of Archibald Kirkland, of Newmains. He was educated at Glasgow High School and Glasgow University, graduating there in 1909. At school he was known as a good footballer, playing for the High School Rugby team. After graduation he spent a year holding house appointments at the Royal Infirmary, Glasgow, and afterwards at the Maternity Hospital. From this time until the outbreak of war he was obtaining experience as locum tenens in private practice with the intention of specialising in gynæcology later. He obtained a commission in the R.A.M.C. in November, 1914, was awarded the Military Cross at the beginning of 1916 for services at the Battle of Loos, and was mentioned in Sir J. French's despatches. He had charge of one of the first clearing stations at Festubert. Excessive strain caused cardiac dilatation and general nervous prostration, on account of which he obtained his discharge from the R.A.M.C., but he determined to join up again and resumed his rank of captain, doing arduous and dangerous work with a field ambulance until he was killed at his post. One who knew Captain Kirkland well writes that the medical profession has lost a member who would have made a good name for himself.

Captain A. ALLAN PARKER, *M.C.*, C.A.M.C., who died of wounds on Oct. 12th at the age of 26 years, was a native of Mimico, Ontario. He graduated in medicine at the University of Toronto in 1914, sailed from Canada in May, 1916, and after arrival in England was posted to Etchinghill. He went to France in December, 1916, and was on the strength of No. 6 Canadian Field Ambulance, serving for short periods as M.O. with a battalion of the 1st Canadian H.A. and the 1st Canadian C.C.S. He was awarded the Military Cross in October, 1917.

ERNEST HOWARD GLENNY, M.R.C.S. ENG.,
LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant E. H. Glenny, who died at Basra on Oct. 9th, aged nearly 27 years, was youngest son of Edward H. Glenny, of Manor Park, London. He was educated at Redland Hill House, Clifton, and at the Leys School, Cambridge, and after passing the London Matriculation Examination he took a special course of business training at Kensington College, from there secured a post in the London School of Economics, and later served in the office of the Industrial Trust, Ltd. Deciding in 1913 to take up medicine, he entered St. Bartholomew's Hospital, London, gained the Willett Medal, and qualified M.R.C.S. and L.R.C.P. in 1917. After three months as house physician there he was called to join the R.A.M.C., and went straight from Blackpool to Mesopotamia, where he was appointed medical officer at No. 3 British General Hospital last March. There he remained until he was removed on Oct. 4th to the Officers' Hospital, Beit Naama, Basra, seriously ill with pleuro-pneumonia, from which he died five days later.



Captain L. E. ROBERTS, A.A.M.C., who was killed in action on August 29th, at the age of 33 years, was son of J. Albert Roberts, of Geelong, Victoria. After a successful career at the Geelong College he obtained a resident scholarship at Ormond College, Melbourne University, which he held during his University course. In athletics he took a keen interest, being a member of his school football and shooting teams. At the University he represented his College and University in football. Completing his medical course some months earlier than usual, he enlisted in August, 1917, spent some time at No. 1 Australian General Hospital, Rouen, and joined the 8th Australian Field Ambulance early in August last. He was fatally wounded by a shell while his battalion was in action near the River Somme, and died some hours later at the C.C.S. at Daours. Though with his division for only a short time, he had already shown himself a man of courage and ability, and his death is keenly felt by his associates.

Second Lieutenant JAMES STUART RICKETTS, R.F.A., who died on Oct. 5th in a French general hospital from wounds received in action on August 29th, was eldest son of the late Dr. T. F. Ricketts. Educated at Oundle, Lieutenant Ricketts passed into Woolwich with a view of joining the Royal Engineers. Prevented by illness from so doing, he decided to adopt his father's profession, and became a medical student at King's College. His health being restored, he volunteered for service in the Air Corps, but failing to pass the final health standard test, he took a cadet nominationship from his old school and obtained his commission early this year. In the short time which he spent on active service he won golden opinions from his superior officers.

THE HONOURS LIST.

The Albert Medal for gallantry in saving life at sea has been awarded to Surg.-Lieut. William Fryer Harvey, R.N.

On June 28th, 1918, two of H.M. torpedo-boat destroyers were in collision, and Surg.-Lieut. Harvey was sent on board the more seriously damaged destroyer in order to render assistance to the injured. On hearing that a stoker petty officer was pinned by the arm in a damaged compartment, Surg.-Lieut. Harvey immediately went down and amputated the arm, this being the only means of freeing the petty officer. The boiler-room at the time was flooded and full of fumes from the escaping oil. This alone constituted a great danger to anyone in the compartment, and Surg.-Lieut. Harvey collapsed from this cause after performing the operation and had to be hauled out of the compartment. Moreover, at any time the ship might have broken in two, and all hands were fallen in on deck, wearing lifebelts, at the time in order to be ready for this eventuality. Surg.-Lieut Harvey displayed the greatest gallantry and disregard of his personal safety in descending into the damaged compartment and continuing to work there amidst the oil fumes at a time when the ship was liable to sink.

"Audi alteram partem."

INFLUENZA AND PREVENTIVE INOCULATION.

To the Editor of THE LANCET.

SIR,—That the conclusions reached at the War Office Conference "on preventive vaccination for influenza" could only be of a tentative character was obvious. Bricks cannot be made without straw, and dogmatic advice on the prevention and cure of a disease cannot be given in the absence of accurate data as to its causation. In these circumstances would it not have been wiser if the committee had made a more frank confession of our present state of ignorance on the subject under discussion, had indicated the lines along which observation and research could most profitably go, and, if it felt constrained to make some practical suggestion in the way of vaccine prophylaxis, might this not have been done in a manner which should lay less claim to specificity for the remedy offered? Is there not present a slight savour of "intensive cultivation" about the whole argument, as though military necessity led to a forcing of the pace? Many of your readers must have been struck by the lack of cogency in the conclusions arrived at by the committee, as published in THE LANCET of Oct. 26th. After stating in § 1 that "there was considerable doubt as to the primary etiological significance of the *Bacillus influenzæ* of Pfeiffer, and ..... the existence of some as yet undiscovered virus must be regarded as possible," they say, in § 2, that "the general question of the employment of a bacterial vaccine for the control *of the incidence* and severity of the epidemic was discussed, and it was unanimously agreed that inoculations with a *suitable* vaccine might be expected to be of value *in both directions.*" (The italics are mine throughout.) The committee then passes on to consider the selection of a "suitable" vaccine, and "it was agreed that the *Bacillus influenzæ*, the pneumococcus, and the streptococcus *only* should be employed" (§ 3). If it should turn out to be true that the primary cause of the present epidemic is some as yet undiscovered virus, the committee fails to make it clear in what way the use of a mixed vaccine of Pfeiffer's bacillus, pneumococcus, and streptococcus can affect *the incidence* of the disease. If it is merely the severity of the disease—as contributed to by secondary infections due to the above-named micro-organisms—that is likely to be influenced beneficially, might not the committee have said as much without losing caste? And might not the committee have confided in us why the veto expressed in the word "*only*" was decided upon?

So far we have at least got definite advice. But now follows a statement which, though calculated to act as a corrective to the empiricism underlying the practical conclusions, suggests that the committee has really very little faith in its own nostrum, at least as a preventive for the present epidemic; for the fulfilment of the conditions laid down as a desideratum in the preparation of the vaccine is likely to take so long a time that it will outlast (I trust) the present outbreak. The desideratum is "that a number of different strains and types of each organism should be utilised in the preparation of the vaccine, and that these strains should have recently been isolated from cases occurring during the present epidemic and should be submitted to strict tests as to race and type *prior to use.*" But despite this considerable qualification, involving highly expert and lengthy technique, the committee proceeds (§ 4) to give "the relative proportions of the different organisms and the dosage of the vaccine," as though all this work of differentiation of "strain" and "type" and "race" had been already done! The formula given does not seem, on the face of it, to be very different from that of a good many vaccine prophylactics for "catarrh," differing chiefly in the absence of *M. catarrhalis*. But this difference does not go far to save the result of the committee's deliberations from coming very near to *ridiculus mus*. In regard to the constitution of the formula, I should like to endorse emphatically the criticism appearing in Dr. John Matthews's letter in THE LANCET of Nov. 2nd as to the suggested dose of Pfeiffer's bacillus. Years ago, when it was very difficult to cultivate this bacillus, and we used fresh blood for the purpose, even then securing very little growth, it was found that small doses of a vaccine made up from such growth often gave smart "reactions." This fact led to the custom of employing a small dosage in general when using Pfeiffer's bacillus either for preventive or for curative vaccination. Whether the "bite" of these older vaccines was due to the admixed blood from the medium, or to "aggressins" or to some other property that seems common to vaccines from most micro-organisms when grown with difficulty, is not known. But it seems certain that vaccines prepared from cultures of Pfeiffer's bacillus grown in profusion upon Matthews's trypsin blood medium are much less innocuous than those prepared from cultures on ordinary blood media. And, although the committee does not expressly say this, it would appear essential that the bacillus should be cultivated upon Matthews's medium in order to obtain sufficient growth for the purpose of such a large quantity of vaccine as is here proposed for military use. During the past two years I have found, in the employment of such vaccine in a series of cases, that the appropriate dosage is quite ten times the size I was formerly in the habit of using.

I am, Sir, yours faithfully,

Harley-street, W., Nov. 3rd, 1918. THOMAS HORDER.

To the Editor of THE LANCET.

SIR,—As some time must elapse before the most suitable prophylactic and therapeutic doses of vaccine for influenza are agreed upon, a brief note upon the experiences of those who have used them should be of service.

Prophylaxis.—I agree with Dr. John Matthews (THE LANCET, Nov. 2nd) that the doses recommended at the War Office Conference are inadequate, and likely to imperil the value of a vaccine. Experience with other diseases teaches that in order to obtain lasting immunity large doses must be given. For typhoid, doses of 1000 million are used. In pneumonia, Sir A. E. Wright suggested a dose of 1000 million for prophylaxis and a dose of 500 million at the outset of a pneumonia attack. Lister in his South African studies went further and used three inoculations at seven days' intervals, each dose consisting of 6000 million cocci of each group against which immunity was desired. I do not know how many strains were used, but probably 18,000 to 24,000 million pneumococci were given in one dose. As compared with these a dose of 30 million *B. influenzæ* seems absurdly inadequate. The period of immunity is probably proportionate to the dose used. Whereas a dose of 1000 million may confer immunity lasting several months, the immunity from a dose of 30 million probably lasts but a few days. 100 million pneumococci and 40 million streptococci are advised as a first dose, but as these are composed of several different strains the actual immunising dose against a particular strain would be as little as 10 or 20 million.

My own plan has been to inject as a first dose 100 million pneumococci, 100 million streptococci, and 50 million *B. influenzæ*, and after seven days double these amounts. A certain number of cases have been injected with pneumococci and *B. influenzæ* only. Such doses probably confer immunity for a few weeks only, but there is no reason why a third or fourth dose, each twice the previous one, should not be injected at weekly intervals. About 200 cases have been injected and these were mainly chosen from contacts—doctors, nurses, relatives of patients. In no case was there a noticeable general reaction. There was no interruption of work, the persons injected followed their ordinary duties. So far I know of no case of influenza occurring in an inoculated person. There was no sign of increased susceptibility, although they were exposed to infection and cases of influenza occurred in non-inoculated persons living in contact with them.

Treatment.—Vaccines are recommended for subacute and chronic cases, but not for severe cases of secondary broncho-pneumonia. The doses recommended are 6 million *B. influenzæ* in subacute cases, and if used in broncho-pneumonia 1½ million. Again, I consider these doses inadequate. Cases of pneumonia and broncho-pneumonia have been treated by vaccines for years. In acute lobar pneumonia I give doses of 100 million pneumococci to an adult man as soon as possible after the onset of the disease. In broncho-pneumonia treatment cannot be given early, as the causal organism must be determined, and in any case smaller doses than the above are advisable. In a series of Friedländer's pneumonia I used doses of 30 to 50 million bacilli with good results. In mixed streptococcic and pneumonic broncho-pneumonias I have

used doses of 30 to 50 million of each organism. With influenza my present plan is to inject 50 million pneumococci, 50 million streptococci, and 30 million *B. influenzæ* as soon after the onset as possible. In no case in which the vaccine was given within 24 hours have lung complications afterwards developed. When broncho-pneumonia has developed before the patient is seen I give the same dose, repeating or even increasing every other day or sometimes daily, and have several striking charts showing the effect of the vaccine in bringing down the temperature and limiting the severity of the disease. I feel sure that similar results cannot be obtained by the use of doses of 1½ million *B. influenzæ*. I would urge the immediate treatment of influenza by giving vaccine in adequate doses within a few hours of the onset. Hesitation and delay allow the cases to get out of hand, and little can be done for the profound toxæmia which is present later.

The letters of Dr. Wm. Collier (THE LANCET, Oct. 26th) and Sir J. W. Moore (Nov. 2nd) on the clinical aspects are very interesting. In my cases epistaxis has been constant in children and young adults, less common in older patients. Albuminuria to some extent has been a constant sign. In the more severe cases there has been a definite nephritis. Bacteriological examination of catheter specimens of urine has usually shown streptococci with frequently *B. coli*. In women patients menstruation is brought on prematurely or there may be hæmorrhage midway between the periods. In the severe cases there is a characteristic facies, swollen and somewhat resembling that of measles without the marked rash of the latter, though a slight morbilliform rash is frequently seen. In one case there was an abundant crop of purpuric spots on the legs. In many ways this type of influenza seems to resemble, apart from the rash, the virulent attacks of measles seen in races that have had no previous experience of that disease. The frequent association of influenza with measles seen during the last two years is also interesting from this point of view. Lieutenant-Colonel Macdonald has recently described an epidemic of purulent bronchitis complicating measles occurring in New Zealand troops in which *B. influenzæ* was found in 72·5 per cent. of cases bacteriologically examined. A vaccine containing 300 million *B. influenzæ* was used with good results. In the spring of this year an outbreak of measles occurred in a large public school. One boy after a severe attack, followed by two days' normal temperature, developed acute suffocative bronchitis and died in 48 hours. *B. influenzæ* was the predominant organism in his sputum. Four other boys developed the same condition, but were promptly treated by a vaccine containing *B. influenzæ* made from the sputum of the fatal case, and recovered.

I am, Sir, yours faithfully,

Birmingham, Nov. 4th, 1918. W. H. WYNN.

To the Editor of THE LANCET.

SIR,—I am inclined to take the view that the primary infection in this epidemic is a streptococcus, for the following reasons:—

(1) *Bacteriological.*—Pfeiffer's bacillus is by no means always present, whereas streptococcus is present both in the mucus of the naso-pharynx and also in the sputum. I made up a vaccine on Oct. 17th from the mucus of the naso-pharynx of an influenza patient; the culture was practically a pure streptococcus, but as the pathologists maintained that the organism was unknown I did not use the vaccine clinically till last week. I now find that a dose of 2 million in an acute case is frequently followed by marked improvement in temperature and general well-being within 24 to 48 hours, but a dose of 4 million in milder cases is followed by a slight reaction, and I have discontinued this dose. I have found that an injection of 2 to 4 million seems to help clear up the recurring temperature at the end of an attack.

(2) *Clinical.*—This epidemic differs from Pfeiffer's bacillus epidemic in that old people seem to escape lightly and the severe nervous symptoms with depression do not follow the attack. The fibrinous bronchitis which is sometimes present is more likely due to a streptococcus than either to a pneumococcus or Pfeiffer's bacillus. I have seen a few cases of fibrinous exudate on children's tonsils, at first suggestive of diphtheria but more characteristic of streptococcus, for there is no real membrane. The pneumonia cases are not like the pneumococcus pneumonias; there is often lobular pneumonia (though I have had some lobar pneumonias) and the sputum is sometimes pure blood.

I have been interested to read what the conference at the War Office decided on Oct. 14th as to preventive inoculation, but I should be afraid of giving 40 million streptococci as a preventive dose during an epidemic in case the individual might be incubating the disease at the time. For example, in one house I gave a preventive inoculation of 4 million streptococcus vaccine to each of six people, one of whom had been nursing a case of influenza pneumonia a few days previously; she was the only one of the six who had any reaction; four hours after the inoculation she felt pain at the lower part of the left side of the chest, and her temperature rose to 100° F. next day, but was normal within 48 hours. The vaccine I have been using I sterilised by incubating for 24 hours with 0·5 per cent. carbolic, so that the dosage is necessarily a small one compared with the vaccine sterilised by heat, as recommended in THE LANCET of Oct. 26th. I notice in that article that a dose of 8 million streptococci is recommended by the War Office Conference in a subacute or chronic case; this would about correspond with my experience, allowing for the different method of sterilisation, although I am inclined to think that 8 million is rather too large a dose to begin with.

I am, Sir, yours faithfully,

Oxford, Nov. 5th, 1918. HENRY T. GILLETT.

THE INFLUENZA EPIDEMIC.

To the Editor of THE LANCET.

SIR,—In your leading article of last week upon the influenza epidemic you discussed the problem whether or not the present epidemic wave ought to have been expected or not. That is a question which I am not now concerned to debate. But I would point to the fact that the present prevailing wave of the epidemic actually *was* expected, whether for good reasons or bad.

On August 5th I sent you an abstract of the results of an organised inquiry which had been made in Germany into the bacteriology of the primary wave of the influenza pandemic which showed itself in the late spring, and invited you, if you thought fit to publish this, to mention that it had been put at your disposal in order to draw the attention of workers in this country to the German experience, and to say that the Medical Research Committee would be grateful if the results obtained in this country might be communicated, so that a similar collation of experience here might be made "with a view to the organisation of such coördinated work as may be found possible for the study of the secondary waves of the infection that are to be expected."

In your issue of August 10th you published this information, but without a statement either of its provenance or of its chief purpose. As a matter of history I would record that I cannot recall meeting any pathologist during last July whose attention had been drawn to the records of the pandemic of 1889–1890, and also to the work done in Europe upon the primary wave of the present pandemic, who did not as a result confidently expect a secondary wave, with probably more serious results, to show itself in this autumn or early winter. I am, Sir, yours faithfully,

WALTER M. FLETCHER.

15, Buckingham-street, Strand, W.C., Nov. 6th, 1918.

*** The letter accompanying the abstract sent to us on August 5th by Sir Walter Fletcher was unfortunately not understood by us.—ED. L.

To the Editor of THE LANCET.

SIR,—There are sentences in your leading article of Nov. 2nd which may, I think, create a false impression upon the minds of some readers. "The experience of all previous epidemics in London is that excessive mortality from influenza in any single epidemic does not continue beyond a period of about six weeks." You may, of course, be using the word "excessive" in some peculiar sense, but it is a fact that in 1891, while the total number of influenza deaths registered in the first quarter of the year for London was 24; during each of the 11 weeks beginning with that terminating on May 2nd at least 37 deaths from primary influenza were recorded, and in eight of these weeks the number was greater than 100, while in the succeeding winter epidemic 30 or more deaths were recorded in each of 12 weeks. "The occurrence of an epidemic of influenza followed by an even more severe epidemic of the same disease within three months is almost unknown." There is much virtue in the "almost."

The summer influenza of 1891 produced 50–60 cases in the Wolsingham division of the Weardale rural district, population 3169, during July; the secondary epidemic, beginning on Oct. 18th, gave rise to about 700 cases.[1] The two great London epidemics of that year were separated by an interval of little more than five months. "Summer epidemics are unusual." Yet even within the period of the Registrar-General's statistics to which you refer there was one considerable summer epidemic, while the outbreak of 1833 culminated between April 24th and May 21st, and the historically famous epidemic of 1782 reached its maximum in June.

Upon the general issue whether, after what happened this summer, an autumn recrudescence was to be expected, I doubt if your judgment will be affirmed by a majority of epidemiologists. The sequence of events in the period commencing with December, 1889, was as follows: There was first in the winter 1889–90 an explosive epidemic, possessing the typical features of a primary outbreak of influenza—viz., an approximately symmetrical distribution in time and close concentration around the maximum—features beautifully displayed in Leichtenstern's graph of the Munich epidemic drawn from notification records. The three secondary epidemics of 1891, 1891–2, and 1893–4, particularly the first, were of a different form—viz., less nearly symmetrical and giving a less lofty flattened curve, the interval between the rise and fall of the curve being much longer than in the primary outbreak.[2] Creighton was of opinion that this feature of recrudescence, the appearance of secondary waves of less prevalent but much more fatal disease, was unprecedented. His conclusion may be too absolute. The year 1676, for instance, had more deaths in London than 1675, which gave material for Sydenham's classical account of epidemic influenza. But even if we accept Creighton's view we shall naturally give much weight to the latest epidemic constitution, that of the "nineties." Nor shall we have any difficulty in interpreting the disparate epidemic forms, a short, sharp, symmetrical outburst suggesting a unitary process, a long drawn-out, skew curve implying the combined action of more than one cause group.

Now the summer epidemic of this year was an excellent example of the quasi-symmetrical type. Having had the opportunity of analysing the incidence upon a large body of men in this country, I can testify to its complete identity of form with that of the primary wave in 1889–90. This having occurred, we should naturally fear that the sequel might be worse than in 1890. If a primary epidemic by ill-luck develops in the summer, then a secondary epidemic having its first chance of appearing in the autumn and winter will, if it do occur, be particularly mortal. The reason is plain; the secondary epidemics of the "nineties" were fatal, partaking, as, perhaps, Sydenham would have put it, of the pneumonic constitution; in modern parlance there was much secondary pneumonia. The influence of season upon respiratory complications needs no discussion.

We might indeed have hoped that the precedent of 1890 would be followed and a year skipped, but we could not be sure that the 1891 example might not be adopted when we should be faced by a serious mortality. This is just what has happened. To have stated in August that it was bound to happen would have argued ignorance of the earlier history; to say that it was very likely to happen and to concert measures for systematically studying the course and alleviating the inconvenience, was plainly the correct procedure. Such a procedure was actually followed in at least two of the great Departments of State, with the result that we shall eventually possess much more accurate epidemiological studies of the recent than of any previous outbreaks. You have unwittingly done some injustice to the many able epidemiologists of this country in suggesting that what has happened either did take, or ought to have taken, them by surprise. The medical officer of health of the County of London in particular, who has been steadily drawing attention to the epidemiological importance of trailing epidemics of influenza since 1913, has just cause for complaint.—I am, Sir, yours faithfully,

MAJOR GREENWOOD,
Captain, R.A.M.C.(T.F.); Reader in Medical Statistics, Univ. London; Director of Medical Research Subsection, Ministry of Munitions Health and Welfare Section).

Nov. 3rd, 1918.

[2] Parsons, op. cit., p. 11.

THE TREATMENT OF INFLUENZA.

WE have received a number of letters dealing with special points in the treatment of influenza.

Surgeon Lieutenant R. Murray Barrow, R.N. (H.M.S. *Canada*), suggests a form of treatment which he has found successful in a recent case which was developing rusty sputum and other signs of pneumonia. Five grains of sodium salicylate dissolved in 8 c.cm. of sterile water were injected into the basilic vein, followed by 1/16 gr. of strychnine hypodermically, the injections being repeated at six-hourly intervals. The relief of pain was immediate, the sputum lost its rusty colour, and the cough practically disappeared within 12 hours.

Dr. Walter Kidd writes: "No doubt the use of permanganate of potash in a saline solution for gargling and sniffing, as recommended by the Local Government Board, is an excellent local disinfectant for lessening the risk of influenza. But is there any respect in which it is not inferior to the use of iodine inhalation for this purpose? The use of tincture of iodine in hot water is, on the one hand, much easier for the majority of persons, including children, and the one process of inhaling this moist vapour reaches effectually both the nasal passages and the pharynx, and on the other its germicidal power is, I believe, considerably greater than that of permanganate of potash."

Dr. R. W. Allen states that the vehicle he uses for the intravenous injection of garlic oil is pure ether. In uncomplicated cases he gives an initial daily dose of ½–1 minim of the oil, and suggests the trial of ½-minim doses twice or thrice daily in cases complicated with pneumonia. He has had no such complicated cases, however, since using the remedy. Severe paroxysms of coughing may follow the injection, due, Dr. Allen believes, to the ether. A draught of cold water gives relief.

Mr. Walter Allingham, M.R.C.S., writes that having proved the antiseptic properties of garlic in his treatment of wounded soldiers he decided to try a non-official preparation known as tri-methenal allylic carbide compound in the treatment of influenza. Since adopting this preparation in 80 consecutive cases, with the exception of two he has had no serious complications; in no case has the temperature remained up over 48 hours, and in many instances a normal temperature has been regained in 24 hours, patients feeling easy and wanting food. Of the two exceptions one was a case of pulmonary tuberculosis and the other had severe gastric symptoms. Before adopting the preparation high temperatures persisted in most cases for 5–6 days, complicated by severe bronchial catarrh and in some instances pneumonia.

Major Geo. Stoker, R.A.M.C., recommends the treatment of pneumonia by the continuous inhalation of oxygen from a gas-bag with a soft rubber nose-piece passing up into one nostril.

INFLUENZA, OR A NEW DISEASE.

To the Editor of THE LANCET.

SIR,—In the interesting leading article in THE LANCET of Oct. 26th summarising the Memorandum of the Local Government Board it is suggested that the present epidemic is similar to the previous pandemic of 1889–92, and also to the pandemics of 1803, 1833, and 1837–38. It may be that the clinical features observed in the epidemics of past years are similar to those seen in the present epidemic, but it is equally certain that many of the cases now seen present clinical features which are quite distinct from the cases of so-called "influenza" or "influenza colds" which we are accustomed to see every year. There are probably various febrile and catarrhal conditions which are, for lack of definite knowledge of their true nature, grouped under the term "influenza." But if this term is accepted for the present epidemic, it is well to be clear about the clinical features seen in many of the cases.

Whilst attached to the Military Hospital, Aylesbury, in the winter of 1915–16 we received a number of cases from Halton Camp which presented well-defined clinical features. The patients were admitted with fever ranging from 102° to 104° F., bronchitis, and toxæmic symptoms. There was in some cases blood-stained sputum, which on microscopic examination showed streptococci as the predominating organism. The cases were frequently fatal, and post mortem the signs were those of a septic capillary bronchitis. Pfeiffer's bacillus was not found in any of these cases, neither in the sputum nor post mortem in the lungs. I was struck by the frequency of these cases occurring in particular huts, and it was remarked that new recruits arriving in these huts were more vulnerable to the disease. I sent in a report on the subject to the War Office describing these cases, with certain recommendations regarding prophylaxis, and it doubtless

received the attention it merited. It did not occur to myself or any of my brother M.O.'s that these cases were "influenza," and the medical officers of Halton Camp did not send them in as "influenza." For want of a better term we labelled them *septic bronchitis*, but there was no doubt in my mind that we had to deal with a definite clinical entity, probably caused by a specific micro-organism or an organism whose virulence had been greatly increased by "*passage*."

I have recently had under my care several cases having clinical features almost identical with the cases I had previously seen at Aylesbury. The following are the clinical features :—

Onset: Sudden, with fever temperature 103–105°, shivering or rigor, pains in the back and limbs. Course: Temperature keeps up for several days, with delirium at night. Cough: Irritable cough with frothy sputum, occasionally blood stained. Frequent symptoms are pharyngitis, dryness of the mouth and throat, and pain in swallowing. I have not noted the slowness of the pulse referred to by Dr. Wm. Collier in THE LANCET of Oct. 26th, but the other symptoms he describes are similar to those seen in my own cases. The milder cases show a fall of temperature in four or five days, the chest symptoms disappear; the more severe cases show great prostration and toxæmic symptoms, with dry tongue, and last a fortnight or more. It is amongst these that the fatal cases are seen. Several members of one household may be attacked; especially does infection extend to persons sleeping in the same room.

In my report to the War Office I laid special stress on overcrowding and the danger of a number of men sleeping in one hut.

Besides this type of case other forms are seen in the present epidemic resembling the ordinary influenzal colds, and cases where patients have got up too soon after an "influenza cold" and have developed pneumonia. But these are quite distinct from those first described, which might be called until their etiology is cleared up "*epidemic septic bronchitis*." What is the nature of these cases? Are they due to Pfeiffer's bacillus or what is the infective agent? Until this is known we shall not be on firm ground regarding treatment.

I am, Sir, yours faithfully,

Wimpole-street, W., Oct. 28th, 1918. J. LANDMAN, M.D.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Wm. Collier's letter in THE LANCET of Oct. 26th under the above heading, judging by the history, symptoms, and physical signs, it would appear that cases of pneumonia now occurring are of two varieties: (1) that occurring during an attack of influenza and following the usual course in such cases; (2) the variety consisting of an almost instantaneous onset in a person previously well as a rule. This latter variety presents the peculiarities mentioned in Dr. Collier's letter, and, in addition, in the cases I have seen, a tendency to looseness of the bowel and very early expectoration of frothy, bright red sputum. This appears to be a different disease.

The last two cases I have seen will serve as an illustration. One man on being asked how long he had been ill replied: "I was knocked endways this morning at 2 A.M., suddenly." The other said: "I hadn't been out of my hammock five minutes when I suddenly collapsed." The tone in which they replied conveyed quite clearly to my mind that they were more than considerably disgusted and surprised at the sudden ruthlessness of the onset of their troubles. Before the day had closed (the first day of their illness) they were both expectorating bright-red sputum, and subsequently showed the symptoms and signs mentioned in Dr. Collier's letter, and, in addition, albuminuria and prolonged delirium.

I am, Sir, yours faithfully,

Eston, Yorkshire, Oct. 31st, 1918. H. B. HILL, M.R.C.P.

PS.—The bacteriological report, dated Nov. 6th, states: "Streptococci, a Gram-positive coccus and diphtheroid bacilli present. No tubercle, no pneumococci, no influenza."

THE "MYSTERIOUS DISEASE" IN AUSTRALIA, 1917.

To the Editor of THE LANCET.

SIR,—It may be of interest to report at the present moment that (as I learn from a personal communication just received) Dr. Breinl is able to confirm, from recent observations, the view expressed by him in the *Medical Journal of Australia*, March 23rd, 1918, that the virus of this disease is identical with that of poliomyelitis. Dr. Breinl's conclusions are based upon pathological and experimental research, and some of his slides will, I hope, shortly arrive in this country. The "mysterious disease" was, clinically, a polio-encephalitis, marked by convulsions and tremors rather than by lethargy; epidemiologically, it appeared first in the spring, affecting children principally; later, adults were implicated. Pathologically, neuronophagia was present, though not abundantly; hæmorrhagic foci were noticed.

Happily, Dr. Breinl's experimental achievements would seem to preclude the possibility of the variations, from "standardised" encephalitis lethargica and from "standardised" poliomyelitis alike, being considered to justify yet another new name, and a new notification entity. Otherwise we might now be hearing of Encephalitis convulsiva, *var.* Australiatica (1917).—I am, Sir, yours faithfully,

Harley-street, W., Oct. 29th, 1918. F. G. CROOKSHANK.

INFLUENZA AND THE DIFFERENTIAL DIAGNOSIS OF SANDFLY FEVER.

To the Editor of THE LANCET.

SIR,—My attention has been called to an annotation in THE LANCET of Sept. 14th, entitled "Sandfly Fever or Influenza." I note that, according to Professor G Sampietro, writing in the *Annali d'Igiene*, there is a belief prevalent in Italy that the epidemic which began in the second half of last May, and was prevalent in Spain, and thence spread over Europe, is identical with the so-called three-day fever or sandfly fever, otherwise known as phlebotomus fever.

I think I may claim to have seen in the Island of Lemnos more than 500 cases of each of these diseases, and feel quite confident in asserting, as the result of my experience of their etiology and clinical course, that such condition constitutes a separate, distinct, and definite clinical entity. The clinical picture as described in THE LANCET of the epidemic in question coincides with my experience, but I notice that no mention is made of a very constant symptom which I have come to regard as quite pathognomonic of the disease—namely, a decided tremor of the tongue which is invariably present during at least some period of its course. No cases of this disease were met with last year, but, on the other hand, I had opportunities of studying many hundreds of cases of phlebotomus fever.

When the first cases of the so-called influenza occurred this year they were at first thought to be cases of phlebotomus (sandfly) fever, but it was soon seen that the symptoms, although having a superficial resemblance, were very different from what we had been accustomed to in the previous year. The most prominent signs and symptoms of each disease may be tabulated thus :—

Phlebotomus Fever.	*"Spanish" Influenza.*
1. Headache, invariably of frontal type with severe pain behind the eyes, especially on movement.	1. Headache, generally frontal, but variable. Post-orbital pain present, but not such a constant or prominent feature.
2. Almost invariable suffusion of conjunctivæ and appearance as of "the morning after."	2. Suffusion of conjunctivæ not often present.
3. A quite distinctive and invariable *white* fur on the tongue, which is *not* tremulous except possibly from other causes.	3. A brown or dirty grey fur on the tongue, which is practically always tremulous at some time during the course of the disease.
4. *Temperature:* Always high at the outset—generally 102°–105° F. Patient nearly always exhibits marks of sandfly bites.	4. *Temperature:* Rarely over 103° and generally about 101°–102° at the outset and often lower. May never exhibit signs of bites.
5. *Pulse:* Invariably slow in proportion to the temperature and rarely more than 100 even with the highest temperature.	5. *Pulse:* Also slow, but not in such marked degree as in phlebotomus fever.
6. *Temper:* Very irritable, especially during convalescence.	6. *Temper:* Not specially irritable.
7. *Appetite:* Almost complete anorexia is characteristic.	7. *Appetite:* Very poor, but not lost.
8. *Pains:* In back and lower limbs.	8. *Pains:* All over, but especially in small of back.

To sum up: Phlebtomus fever can be diagnosed at sight, especially in districts where the phlebotomus fly is known to abound, by the two or three most prominent symptoms—viz., blear-eyed appearance of the patient, flushed face, *white* fur on the tongue, and slow pulse with high temperature. No tremor of the tongue. It may be noted that with only three or four exceptions all cases of phlebotomus fever have occurred in men living ashore, the exceptions being in men who were borne in ships anchored close to the beach and undoubtedly infected by sandflies blown off from the beach.

which is known to be possible as sandflies have been found on board these ships though not on others further removed from the shore. Very numerous cases of "Spanish" influenza (in one large ship over 600 cases) have occurred in ships anchored far away from the beach and not accessible to sandflies, though subject to infection by those previously infected or already sickening for the disease known as Spanish influenza.

Phlebotomus fever is, in my experience, decidedly not an infectious disease in the ordinary sense—but only through the agency of sandflies. "Spanish" influenza is, in my experience, certainly an infectious disease, and the spread of infected can be diminished to a very large extent by careful antiseptic treatment of the mouth and naso-pharynx of those already infected, or likely to be infected during the course of an epidemic such as we have recently experienced.

I am, Sir, yours faithfully,

W. BASTIAN,
Surgeon Commander, R.N.

Oct. 12th, 1918.

RICKETS AND HOUSE INFECTION.

To the Editor of THE LANCET.

SIR,—In the Report recently published by the Medical Research Committee "of an inquiry into the social and economic factors in the causation of rickets" it is stated that while we are still ignorant of the cause of rickets, the evidence at our disposal gives little support to the idea that rickets is due to dietetic error. Rather the report lays emphasis upon the connexion of the disease with the factors of overcrowding, want of air and sunshine, and lack of exercise. To me it seems that not sufficient attention has been paid to the manner in which these prejudicial influences act, whether directly upon the nutrition of the child, or indirectly by lowering his immunity against infection, and so multiplying the incidence of transient pyrexial processes of all sorts. It is the object of this letter to suggest that this latter factor, which finds no place in this careful and elaborate report, is of too great importance to be excluded from such a discussion.

No one who comes much in contact with the children of the poor can be in doubt as to the frequency of catarrhal infections of the respiratory tract. Of many of these children in the first year of life it may be said that no single month passes without one or more bouts of pyrexia from this cause accompanied by severe loss of weight and a great diminution of vigour and activity. Crowded together, overfed or unsuitably fed, shut off from sun and air, the children fall a ready prey to such infections, and react with symptoms the severity of which is immeasurably greater than in the sturdy child whose hygiene is not at fault.

The effect upon the child of repeated catarrhal infections.—The loss of weight in such cases may be both great and rapid. Not infrequently within a day or two it may amount to as much as 1/10 of the body weight, a loss which can only be accounted for by an increased excretion of salts and water from the body. The prejudicial effect of such fluctuations upon the cells composing the different tissues of the body may be seen in various ways. For example, in the healthy child the physiological stimulus of the erupting tooth is by no means sufficient to provoke an inflammatory reaction in the surrounding cells of the gum, and the cutting of the tooth proceeds without symptoms of discomfort. If, however, the vitality of these cells is lowered by coincident catarrhal infection of the bowel or of the bronchi, the erupting tooth may be surrounded by a painful areola of inflamed gum. As the mothers tell us, such a child "cuts his teeth with bronchitis or with diarrhœa." In reality it is the coincident bronchitis or enteritis which has increased the vulnerability of the cells composing the gum.

We see the same excessive local reaction in children suffering from catarrhal infections in the little fissures which appear at the corners of the mouth from contact with the tongue, which the French call *perlèche*, or in the painful irritation in the skin of the prepuce where it comes in contact with the urine, or in the napkin dermatitis produced by contact with stools not in themselves highly or unusually irritating. In all such cases the extent of the local reaction is in a sense an index of the diminished vitality and increased vulnerability of the cellular elements of the part. With recovery from the infection and with renewed growth and vigour of the child we can confidently predict a rapid improvement in the local disturbance.

It is not only in these superficial and visible parts of the body that it is possible to detect a rapid deterioration in the vitality of the constituent cells as a consequence of a persistent infective process elsewhere. In structures more deeply situated we can also note the ill-effect. In the muscles we find a rapid wasting and loss of tone. A child of two years, who suffered from a severe nasal catarrh sufficient to cause moderate pyrexia for four days, was unable thereafter to climb a little steep grassy bank, which before had presented no difficulties to him, until the end of the fourth week after his illness. With repeated catarrhal infections the want of tone and flabbiness of the muscles become persistent.

The vaso-motor system also provides evidence. Excessive perspiration, coldness and blueness of the extremities, and undue pallor of the skin persist long after repeated or continued pyrexial infection. The appearance of pallor is due to this vaso-motor instability rather than to a true anæmia. The children flush readily during crying or upon exertion, but without this stimulus the skin of the face is apt to be pale and bloodless.

The prejudicial effects upon the nervous system are shown by the tendency to convulsions, laryngismus, tetany, and so forth, as well as by the loss of coördination in movement or the exhaustion shown in the immobility of the child. Some of these children, exhausted by repeated catarrhal infections, will remain motionless and set in any unnatural posture in which we have placed them for many minutes at a time, a condition which recalls the katatonia of dementia præcox.

In the various ductless glands we find, also, a diminished activity. A long-continued succession of pyrexial infections is apt to leave a child infantile in body and mind, so that sometimes the suggestion of hypothyroidism is apt to occur to us.

The enamel organ of the teeth provides a good example of the ill-effect of pyrexial disorders. Let the child pass through the first two years of life free from repeated catarrhal infection, and it will cut teeth covered everywhere with flawless enamel. But if the activity of the enamel organ is from time to time inhibited by acute infective processes the teeth, when they come, will bear upon them the marks of the vicissitudes through which they have passed in the shape of the so-called circular caries.

Lastly, one may instance the well-known transverse ridges on the nails, following devitalisation of the matrix of the nail by pyrexial processes—markings which are very frequently seen in young children.

The effect of catarrhal infection upon ossification.—If it be granted that the effect of repeated pyrexial infection upon cutaneous, muscular, and nervous tissues is as described, it would be strange if skeletal tissues were to be excluded. The activity of the osteoblasts also is inhibited by repeated pyrexial illness. The close association of catarrhal processes of all sorts with the rickety state has not, of course, escaped attention, but it has been usual to represent the tendency to catarrhs as the result of rickets, and thus to deprive it of etiological significance. As the present report reminds us, we owe the earliest accurate description of rickets to Glisson. Nor is it surprising that in this disease of domestication, this perversion of growth due to want of sun and air, lack of exercise, and faulty feeding, it should be the changes in the rigid skeleton which should first catch the eye of the early observer. The prominence first conceded by Glisson to the skeletal changes has been maintained by all subsequent writers.

That the environmental faults incriminated may directly and of themselves produce sufficient interference with nutrition to provoke all the symptoms of defective cellular activity both in the bones and in other tissues I do not deny. It is even likely that any one such fault, if it be sufficiently concentrated, may at times and in experiments upon animals be itself capable of producing rickets. In general, however, I believe that these factors act as predisposing causes by lowering the immunity against infection, and that it is in consequence of the infection that the rickety process develops.

The age incidence of rickets.—To this view of the importance of infection of the child in the production of rickets an objection may be made that the incidence of catarrhal

infections extends all through childhood, while rickets is common only within certain well-defined age limits. In childhood, however, we recognise certain well-marked stages of development. In the first few months of life it is the digestive function which is so hypertrophied that it attracts all attention to itself, so that infections of all sorts, as, for instance, the common infectious cold which sometimes passes through a whole household, are apt to take on themselves the appearance of primary alimentary disorders. Later locomotion and the increased activity of the bone-forming elements which takes place under the stimulus of walking become in turn prominent. How great is the change in the skeleton which the assumption of the upright posture and the stimulus of walking produce. The legs, which up to that time have been active, if somewhat inefficient, prehensile organs, become modified into organs of support. The pelvis and the chest undergo a rapid expansion, the abdomen relatively recedes, and the curves of the spine are altered. If, however, as a result of repeated or persistent infection the motor activities of brain, nerve, and muscle are inhibited, this moulding of the skeleton is delayed and in bad cases prevented. This period of high functional activity and the period of the increased liability to rickets correspond. Within this age limit a high proportion of infected children develops some signs of rickets. That many escape is to be expected. Similarly, the syphilitic toxin, which in general shows the same affinity for the epiphyses, is often content to leave the bony system unaffected.

Calcium metabolism in rickets.—That pyrexial disturbances in infancy and childhood are accompanied by profound alterations in the retention and excretion of salts is shown by the great and sudden fluctuations in the body weight. In certain children convulsions and tetany, accompanied often by œdema of the extremities, are almost invariable accompaniments of a pyrexial attack, and it is significant that a very large proportion of children with tetany are also rickety.

Experiments upon calcium metabolism in rickets have given very contradictory results. In most cases the research period has been as short as three or four days, and it is clear that in a disorder of such long duration as rickets little information of value can be obtained from the mere presence or absence of a negative calcium balance in that short period. I know of no work which has been undertaken to estimate the calcium balance of rickety children suffering from pyrexia. On the general question, however, of the calcium metabolism during pyrexia, it would appear that excretion may be increased.

Rival views of the origin of rickets.—There is at the present time some tendency for a sharp difference of opinion to arise as to the cause of rickets. There are those who hold that the disorder is a "diet deficiency" disease; there are others who will have none of this view, and regard it as a disease of "domestication or urbanisation." Dr. Leonard Findlay has shown the ill-effect of confinement and lack of exercise in puppies. Dr. Eric Pritchard has emphasised the evils of over-feeding. The cause has even been found in hypothyroidism, and the thyroid as well as other ductless glands have been implicated. If rickets be no more than the temporary inhibition of osteoblastic activity during infective processes of all sorts, upsetting the balance which maintains in health between osteoblast and osteoclast, if the softening of the bones is comparable to the accompanying amyotonia, to the devitalisation of the skin and mucous membranes, to the irritation and exhaustion of nervous tissue, and to the diminished activity of ductless glands, then we can accept all of these rival claims as playing a part in lowering the immunity of the child against infection. The child who is fed upon an excess of carbohydrate food, the child who is kept away from fresh air and sun and who has no opportunity for free movement, and who is in close contact with infected persons is prone to frequent if transient infection. In our study of such a disorder as rickets we must not omit to keep the child himself in the foreground. We must attempt to isolate and weigh the effects even of such *imponderabilia* as the common and frequently repeated household cold. An analysis of the symptoms ordinarily attributed to rickets such as is presented in the report by Dr. Findlay is historically interesting, and a survey of the social and economic factors such as Miss Ferguson contributes is of the very highest practical utility. It is, however, the reaction of the child to the evils which she discloses which demands closer study. If from such a study we are able to shift our ground a little and regard as the factor of chief etiological significance not the refusal of the osteoid tissue to undergo ossification, but the lowering of immunity and the repetition of catarrhal infections of the respiratory and alimentary tracts, then we shall have less reason to dispute as to the importance of rival "causes of rickets." For all will then be recognised as important and we shall have an explanation in keeping with the coincident changes in other tissues of the body, changes which are clearly the result and not the cause of the state of infection. I am, Sir, yours faithfully,

Devonshire-place, W., Nov. 2nd, 1918. H. CHARLES CAMERON.

ACCESSORY FOOD FACTORS IN INFANT FEEDING.

To the Editor of THE LANCET.

SIR,—In his extremely interesting contribution to THE LANCET of Oct. 12th on the subject of infant feeding Dr. J. C. Drummond refers to the use of Marylebone cream in combination with separated dried milk as a food for babies, and states that he would expect to find that children fed on such a mixture would show diminished resistance to disease in spite of apparent normal development. As I have had some five or six years' experience of feeding infants at my centre in accordance with this method, my experience may not be without interest.

I have not had much experience with the use of ordinary Marylebone cream (made with linseed oil) in combination with dried separated milk, because after a short trial I gave it up for the very reasons predicted by Dr. Drummond, but I have had some experience of "modified" Marylebone cream, used with separated milk, and the results have been excellent. "Modified" Marylebone cream is made from soya-bean oil; cotton-seed oil and suet in such proportions that the resulting combination contains approximately the same percentage of the neutral fats, olein palmatin, and stearin as butter fat contains. I thoroughly endorse Dr. Drummond's view that the real criterion of good nutrition is resistance to disease. Judged on this ground, I find that infants fed on dried separated milk modified to the standard of breast-milk with sugar and Marylebone cream of the above variety compare not unfavourably with artificially fed infants reared on other dietaries, in spite of the fact they are drawn from the poorest class of infants attending at the consultations. I may add, however, that these infants, in common with all other hand-fed infants attending at my centre, are invariably provided with three other accessory food elements—namely, with the "water-soluble C" element by giving fruit-juice or turnip-juice, with the "water-soluble B" element by giving daily 1 oz. of meat and vegetable broth, and with lecithin bodies by giving daily either a small quantity of the yelk of egg or a few grains of glycerophosphate of calcium, which seems to answer the same purpose in lending stability to the nerve cell.

I have been using dried milks of all kinds during the last ten years for infant feeding, at first without the addition of these accessory factors and for the last five years in combination with them; the results are, in my opinion, astonishingly better when the accessory factors are added.

I am, Sir, yours faithfully,

Harley-street, W., Nov. 1st, 1918. ERIC PRITCHARD.

NASAL DISINFECTION.

To the Editor of THE LANCET.

SIR,—There is a large group of infectious diseases in which the infective organisms live and apparently multiply in the naso-pharynx and the accessory sinuses. Typical instances of these diseases are scarlet fever, diphtheria, and cerebro-spinal fever. The organisms are found sometimes in patients who have suffered from the disease, sometimes in healthy carriers. They often persist for a long time, are difficult to destroy, and are a frequent cause of spread of infection, especially when a nasal discharge occurs. My own experience has been almost entirely in connexion with scarlet fever and diphtheria as treated in hospital, and in these diseases the difficulty of getting rid of infection is notorious. Antiseptics, applied by spraying, syringing, inhalation, or otherwise, have all failed, and it almost

seemed as if the best that could be done was to put the patient under the healthiest possible conditions and rely on fresh air and ordinary hygienic measures, in the hope that in time the organisms would die out. Usually they did so, but sometimes the naso-pharynx seemed to act as an incubator and the organisms continued to multiply, while sometimes, after almost disappearing, they seemed to take on a new lease of life, possibly under the influence of some morbid condition of the mucous membrane.

The main difficulty in treatment is that the naso-pharynx and its accessory sinuses form such an intricate series of chambers that it is impossible to cleanse them from the outside; and to obtain complete success every part must be reached. This being the case, it occurred to me that the correct line of treatment would be to imitate the natural method and try to wash out all the passages from the inside by causing increased secretion; and some years ago I began to employ menthol inhalation. A solution of menthol ℥i. in ℥viii. of spirit, with a few drops of eucalyptus oil, was used, one or two drachms of this being added to a pint of very hot water in a jug. The patient held his head, covered by a towel, over this mixture for some minutes and sniffed vigorously, inhaling the somewhat irritating vapour, and so causing a free discharge from the nose. The procedure was repeated from three to six times daily. It is not particularly pleasant, but children usually submit to it readily enough if coaxed. It is essential to success that there should be a free discharge of mucus, and this may be assisted by blowing the nose.

The results of this simple method of treatment, if properly tried and persevered with, are, in my opinion, very satisfactory and superior to other methods for getting rid of organisms. They are most easily studied in the case of nasal diphtheria, as here the organisms are distinctive and readily recognised. In this disease I have repeatedly seen the menthol treatment cause a disappearance of the bacilli in old-standing cases. Not infrequently it happens that before disappearing the bacilli alter in character. They lose their beading, become shorter, and assume the characters of the Hofmann type. A drawback to the treatment is that if the patient is a young child he must be carefully looked after during the inhalation, otherwise he might scald himself, and it might be feasible to make use of an inhaling room similar to that employed in the Army for the administration of antiseptics to carriers of the meningococcus.

As regards the prophylactic value of the treatment I have no experience, but it is not unreasonable to expect benefit from a treatment which tends to produce bacteriological cleanliness of the nasal passages. During a time of epidemic prevalence of such diseases as influenza or after definite exposure to infection it might be of service to supplement the ordinary toilet of the teeth and mouth with a menthol toilet of the nose. Numerous organisms are inhaled through the nose and many remain for some time lodged on the surface of the mucous membrane. It is quite possible that disease might be prevented by washing away these organisms before they have time to cause mischief. Gargling, too, may be useful, especially in the case of mouth-breathers. But, surely, if breathing is carried on in the proper way through the nose and if organisms are entering with the inspired air it is a little illogical to employ a gargle for the throat, while the cleansing of the nose is ignored.

I am, Sir, yours faithfully,

F. J. WOOLLACOTT, M.D. Oxon., D.P.H.

Hampden-street, N.W., Oct. 26th, 1918.

THE BENEFITS OF "NASAL DRILL."

To the Editor of THE LANCET.

SIR,—I wish to give my rather belated support to Dr. Isabel Ormiston's article in your issue of August 24th describing a new method in the treatment and prevention of adenoids. Dr. William Ewart and Dr. Leonard Williams have in subsequent letters indicated wider aspects of this simple and physiological "nasal drill." The unnatural structural changes which would follow from a damming-back of nasal and pharyngeal secretion seem to be the explanatory groundwork of vegetations, polypi, atrophic change, and tonsillar hypertrophy. When the function of mucous glands is in abeyance, and to this are added deviations and spurs of the nasal septum due to trauma or other causes, it is not difficult to understand why the turbinal bones should become diseased, why the complicated processes of the ethmoid should tend to sepsis, why the entrance to the antrum should become occluded, and why atrophic rhinitis and disease of the nasal septum should arise. If we superadd to all this an unsuitable environment and a social custom which decrees that the nose shall be blown in a quiet and decorous fashion, we can comprehend the chief amongst the causes of diseases of the nose and naso-pharynx.

I have had the privilege of watching patients treated by Mrs. E. Hancock's novel but natural method, and have noticed particularly the prompt disappearance of those symptoms which appear latest in cases of nasal and naso-pharyngeal catarrhal obstruction. When the treatment is continued and the drainage of mucus from the nose and naso-pharynx continues for weeks, the improvement in general health and psychical well-being becomes gradually apparent.

Following the simple technique described in Dr. Ormiston's letter, I experimented for two months while at a base hospital in France and cite the two following cases:—

M. A., aged 31 years, had chronic atrophic rhinitis of about six months' duration. The case was a favourable one, as it was in an early stage. Examination showed that the nasal septum was perforated from side to side, apparently by trauma—a small nail thrust into the nose in childhood. The nasal cavity was over-ventilated, the nostrils were widened, the mucosa being dry and atrophic. Crusts had formed over certain areas and there was some ozæna. Patient admitted that he used his handkerchief rarely and always ineffectively and that he had not sneezed for a long time. Treatment over several weeks restored temporarily the sneezing habit and induced a copious flow of mucus. The ozæna disappeared early, the crusts gradually disintegrated, and the nasal mucosa became moister and healthier. After three months' interrupted treatment the crusts had completely disappeared and the general health of the patient was much improved.

In this instance there was at first slight conjunctivitis of the eyes, an icteric tinge of the sclerotic, and a considerable error of refraction. The conjunctivitis and the icterus disappeared, and the patient stated that his eyes were distinctly benefited by the restoration of nasal function. He is now, after two years, permanently free from any signs of atrophic rhinitis. The error of refraction, of course, remains unaffected.

F. B., aged 23 years, had two small polypi visible as stalked processes between the middle and inferior turbinal bones of the left side. Adenoid vegetations were also present. Headaches, "stuffiness," retention of discharge and overflow of mucus into the pharynx, broken sleep, and a "constant cold" were the complaints of the patient. An enormous amount of mucus was drained from the nose and naso-pharynx by treatment at intervals over a period of six weeks. The polypi gradually decreased in size until they had disappeared. Headaches, "stuffiness," and sleeplessness were abolished after a week.

It is very gratifying to know that "nasal drill" has become an accomplished fact in at least one children's school in London and that Mrs. Hancock's method is growing in popularity.

I am, Sir, yours faithfully,

A. L. MCLEAN, M.D.,

Oct. 23rd, 1918. Captain, A.A.M.C.

NOTIFICATION OF INDIGENOUS MALARIA.

To the Editor of THE LANCET.

SIR,—I may be an optimist, but judging by previous experience I think it is extremely unlikely that malaria will cause much trouble in England when the war ceases. Practically everybody who spends any time in the tropics gets malaria some time or other, and for very many years we have had thousands of men coming back to live either in barracks or else in fairly crowded civil habitations all over the British Isles. Anopheline mosquitoes can be found in many places, and yet cases of indigenous malaria have apparently been extremely rare, and I have never heard of more than one case reported in the same place and year.

Recently a case occurred in my Division in France, but here the line from May to the end of August was in the midst of water channels where thousands of mosquitoes were being bred. I did not think it worth while to recommend any preventive measures, and this was justified, as no further cases occurred. For any serious spread of this disease a large number of infected men and mosquitoes is required, and probably also a continuous spell of really hot weather such as is extremely rare in England. Although malaria is well known to recur in some cases for several years, in the vast majority recurrences are comparatively rare after a few months' residence in a temperate climate; and it may be remembered that when Ross was carrying out his researches his infected birds lost their parasites when he moved from the plains to the more genial climate of the hills.

Should cases of indigenous malaria ever become more prevalent I think they should be notified, as medical men

without tropical experience are naturally not inclined to take the disease into consideration when a diagnosis is being made; and proper treatment is likely to be delayed, especially as the parasite may not be found on first examination. On getting fever some years ago in India—chiefly out of curiosity to get a correct diagnosis—I determined not to take quinine until I had found the parasite; and this I did not succeed in doing until the third onset had occurred. Similarly, I remember seeing an "interesting" case of pyrexia in an Indian hospital in which malaria was excluded as parasites had not been found on first examination. Pyrexia had lasted several days, but when I suggested re-examination of the blood numerous parasites were found, and all signs and symptoms cleared up at once on administration of quinine.—I am, Sirs, yours faithfully,

N. FAICHNIE,
Lieut.-Col. (temp. Col.), A.D.M.S., "X" Division.
B.E.F., France, Oct. 22nd, 1918.

ADDITIONAL FUEL IN CHILDBIRTH.

To the Editor of THE LANCET.

SIR,—I beg to enclose herewith a copy of a letter received from the Controller of Coal Mines, to which I hope you will be able to give publicity.—I am, Sir, yours faithfully,

J. HALFORD,
Secretary, National League for Health, Maternity and Child Welfare, including the National League for Physical Education and Improvement.
4, Tavistock-square, London, W.C. 1, Oct. 29th, 1918.

[ENCLOSURE.]

Board of Trade, Coal Mines Department: Household Fuel and Lighting Branch.

Holborn Viaduct Hotel, London, E.C. 1, Oct. 11th, 1918.
Subject—Additional Allowance under the Household Fuel and Lighting Order, 1918.

DEAR MADAM,—Replying to your letter of the 9th October, I am directed to say that a claim could certainly be submitted for an additional allowance on the ground of illness in the case of childbirth, and would be allowed for a reasonable period thereafter. The maximum quantity of fuel that may be granted on such a claim is five tons, but it is felt that the decision as to the actual quantity that would be granted must depend on the circumstances of the particular case.

I am, yours faithfully,
W. H. GAUNT,
For the Controller of Coal Mines.
Miss Halford, Secretary, 4, Tavistock-square, W.C. 1.

A CASE OF ABSENCE OF SENSATION.

To the Editor of THE LANCET.

SIR,—I was greatly interested in Captain E. D. Roberts's paper in your issue of Oct. 19th on a case of absence of all sensation, and in your annotation on the same subject in the same issue. Since the subject of this paper left Aldershot Military Isolation Hospital he has been in two of our Canadian hospitals, and is still an inmate, and I have had an opportunity of studying his case. In the main Captain Roberts's very clear description of the condition of the patient still holds good, but there are several changes both in the history of the case as given by the man himself and in his present condition, and these changes in themselves throw a certain amount of light on the diagnosis.

The patient was admitted to our hospitals under a diagnosis of I.C.T. (inflammation connective tissues), and his forearms show many scars and scabs where he himself or interested friends have burnt the skin with lighted cigarettes in order to test his sense of pain. Contrary to what Captain Roberts found, the man assures me that he was quite well until he had yellow fever at the age of 17 (i.e., 20 years ago), and that he has been in the present state ever since. Captain Roberts laid some stress on the fact that the patient could swim well, but he tells me that he never could swim a stroke and always "sank like a stone" when he tried to do so; so evidently he tells a different tale at different times. The senses of pain, touch, heat and cold, taste and smell, appear to be quite absent everywhere, but, strange to say, the man is very fond of smoking. He told me that this morning he ate a very bad egg for breakfast and "did not mind"; he seemed, indeed, very proud of the fact.

As regards absence of muscular sense, I have some doubt. If the patient be blindfolded and laid flat on his back on the ground and then be told to rise he does not move, and says that he cannot do so unless he can see, but when he is passively raised into a vertical position he stands steadily, and if given a push maintains his equilibrium, which suggests the presence of muscular sense. We could not get him to walk blindfolded. Again, as regards the sense of weight. If a light object, such as an empty match-box, be placed in one extended hand, and a heavier one, such as an empty glass ink-pot, in the other, the patient says that he cannot feel them there, let alone say which is the heavier. If now either object be pressed downwards to the extent of many pounds pressure, he can be felt to resist violently, which suggests a conscious or subconscious knowledge of the increased weight with consequent resistance, and yet he says that he does not know which is the heavier. He does not seem to have the sense of position of his limbs. When the eyes are closed and when the arms or legs are placed in elevated positions they now at once fall, and there is no suggestion of catalepsy. When told to keep his eyes closed there is constant blepharo-spasm, which is suggestive.

This man has been a show case at many hospitals in America and France for many years, and has apparently become quite fixed in his ideas. From the fact that the senses of touch, smell, and taste are absent, as well as those of pain and heat and cold, we can probably rule out syringomyelia. The anæsthesia is not dissociated. In syringomyelia the senses of pain and of heat and cold are usually the only ones involved, and, moreover, generally this is over only certain areas. In this case the whole body is implicated. Again, in syringomyelia there is usually some spasticity of the legs, with trophic disturbances of the skin, muscles, or joints, and not infrequently some muscular atrophy. All these are absent here.

To my mind the case is one of pure hysteria. It is, nevertheless, of great interest on account of its profound nature and long duration, and Captain Roberts did well to put it on record. The patient tells me that he has had two brothers killed already in the French Army, but I fancy that the chances of his being of much good as a soldier are small. He is too interesting a case!

I am, Sir, yours faithfully,
R. D. RUDOLF,
Colonel, Consulting Physician, Canadian Forces in England.
Oct. 24th, 1918.

MEDICAL RECONSTRUCTION.

To the Editor of THE LANCET.

SIR,—On two points of Sir W. Watson Cheyne's letter in THE LANCET of Oct. 12th I feel constrained to trouble you. He writes about those civilians whose practices have disappeared during service in the Army. Surely a number of those practices have disappeared because of, not in spite of, the services of their neighbours and should therefore be capable of replacement. I have in mind particularly the case of the elderly (territorial and temporary commissioned) officers with families who have had to give up all practice on account of the war, and whose practices have "disappeared." Is it not "up to" the profession to see that they are reinstated completely? Can no pressure be brought to bear upon the persons who have filched their means of livelihood to restore it either in money or kind? I know this cannot be done by means of the law, but is there no other means of bringing these people to book, or do the B.M.A. shirk the work because it is unpleasant?

Would it not be better to raise a fund to set these men on their feet again without any question of repayment rather than to insult them by offering to lend them money (a bank can do that) in order that they may themselves repair the injury caused by the Hun and their fellow practitioners?

This matter does not affect me personally, either as "robber" or "robbed"; but I do feel that for the honour of our profession something should be done, and done quickly, and any fund raised (not for loans but for restitution) will receive my mite at once.

I am, Sir, yours faithfully,
R.A.M.C. (T.C.)
Oct. 12th, 1918.

To the Editor of THE LANCET.

SIR,—There is a considerable amount of correspondence at present on the future of the medical profession. Some eminent men have given their ideas as to what should be its future. It does not appear to have occurred to any of the members of the profession at home that there is a considerable number of doctors now serving in the Navy and Army, or that these men will one day, if they survive, return to civil life. Many of them left their practices at the beginning of the war. These practices have been absorbed by those that remained. It is natural that those who have been making a great deal of money during the war, and hope to continue to do so, should desire that the present conditions of medical practice should continue, and that a State

Medical Service should not come into being. Under such a scheme they stand to lose money.

But what about the men who have lost all owing to their patriotism, and have nothing to return to? Some of us will have been away for five or six years. I have served in several theatres of war, and have not met a medical officer who is not in favour of a State service.

Surely the opinion of the more patriotic part of the profession and their interests are deserving of some consideration? The best are abroad and likely to remain there for some time to come. When they return there should be Government billets ready for them, and they should not have to compete with the men who have taken their practices from them.—I am, Sir, yours faithfully,

Sept. 25th, 1918. LIEUTENANT-COLONEL, R.A.M.C. (T.F.)

THE SERVICES.

ROYAL NAVAL MEDICAL SERVICE.

To be temporary Surgeon-Lieutenants: J. H. E. Ewen, C. C. R. Downing, G. Millar, F. P. N. Parsons, W. L. Berry.

ARMY MEDICAL SERVICE.

Col. J. M. F. Shine is placed on retired pay.

Lieut.-Col. (temp. Col.) G. W. Tate, from R.A.M.C., to be Colonel.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Col. G. M. Goldsmith to be acting Colonel whilst employed as Assistant Director of Medical Services of a Division.

Temp. Major A. M. Leake, V.C., relinquishes the acting rank of Lieutenant-Colonel on re-posting.

Majors to be acting Lieutenant-Colonels: R. W. D. Leslie (whilst employed as Assistant Director of Medical Services), A. H. McN. Mitchell (whilst in command of a Medical Unit).

Temp. Major A. F. Hurst to be acting Lieutenant-Colonel whilst specially employed.

Capt. (temp. Major) R. Hemphill to be acting Lieutenant-Colonel whilst in command of a Field Ambulance.

Temp. Capt. F. G. W. Deane to be acting Lieutenant-Colonel whilst specially employed.

Temporary Captains to be acting Majors whilst specially employed: A. Dingwall-Fordyce, C. H. Fennell, R. Milne, W. N. Parker, N. C. Lake, W. S. McGowan, D. I. Anderson, T. Russell.

A. E. Morison to be temporary Major whilst employed at Sunderland War Hospital.

Temp. Capt. D. P. Hanington, Canadian Army Medical Corps, to be acting Major while employed as Registrar, Canadian General Hospital.

The undermentioned relinquish the acting rank of Major on re-posting: Capts. G. O. Chambers, J. Y. Moore; Temp. Capts. A. K. Cosgrove, H. H. White, C. C. Court, D. I. Anderson.

To be acting Majors: Capts. H. G. Trayer, J. R. Lloyd, R. E. Gibson, C. R. Dudgeon; Temp. Capts. J. L. A. Grout, J. Jack, C. F. Knight, A. W. Dennis, R. Warren, F. Henderson, A. M. Crawford, W. Anderson.

Lieutenants (temporary Captains) to be Captains: R. D. Davy, R. L. Ritchie, R. B. Myles, E. S. Cuthbert.

F. M. Murray and H. C. Smyth (late temporary Captains) are granted the honorary rank of Captain.

Temporary Lieutenants to be temporary Captains: W. Fletcher-Barrett, W. B. Dove, W. V. Naish, B. R. Vickers, J. A. C. Smith.

Temp. Lieuts. H. J. Starling and J. R. Hewetson to be temporary Captains.

Temp. Hon. Lieut. S. R. Meaker to be temporary honorary Captain.

Officers relinquishing their commissions: Temp. Hon. Maj. W. P. S. Branson, on ceasing to be employed with No. 1 Red Cross (Duchess of Westminster's) Hospital; Temp. Capts. E. S. Hall, J. H. Wilks, W. Lumley, B. Lyons, J. G. Milne, R. G. Abercrombie, T. E. Mulvaney, A. N. Collier (on account of ill-health), S. J. McC. Bradshaw, J. Brown, A. W. Brodribb, F. W. Stone, C. L. McDonagh, C. T. Galbraith, E. C. Arnold, W. F. Moore; Temp. Hon. Capts. (on ceasing to serve with No. 22 General Hospital) E. D. Busby, G. W. Cottis; Temp. Lieuts. L. G. Allan, B. Blackwood, G. E. J. Greene, P. Liston; Temp. Hon. Lieuts. (on ceasing to be employed with No. 22 General Hospital) W. M. Findley, J. E. Bloomer.

GENERAL RESERVE OF OFFICERS.

Major H. S. Peeke relinquishes the acting rank of Lieutenant-Colonel on ceasing duty with No. 1 British Red Cross (Duchess of Westminster's) Hospital.

SPECIAL RESERVE OF OFFICERS.

Capts. H. M. Williams and A. J. Clark relinquish the acting rank of Major on re-posting.

Capt. G. K. Aubrey, from temporary retired pay, relinquishes his commission on account of ill-health contracted on active service, and is granted the honorary rank of Captain.

Captains to be acting Majors: R. Mackinnon, J. A. Ryle, P. J. Gaffikin.

Lieutenants to be Captains: W. L. Yell, J. B. D. Galbraith, I. M. Robertson, T. R. Wilson, J. P. White, J. Macleod, A. Riddell, J. J. A. Scott, F. J. Harvey, D. J. Valentine, S. H. de G. Pritchard, F. W. A. Watt, W. M. Jones, A. G. F. McArthur, S. W. Page, L. K. Ledger, M. Edwards, A. McL. Pickup, O. C. Carter, W. U. Longford, M. J. Hilton, C. S. Baxter, W. S. Stansfield.

To be Lieutenants: J. Lipsey (from Glasgow University Contingent, O.T.C.), L. J. Schwartz (from University of Manchester Contingent, O.T.C.), M. Melvin (from Edinburgh University Contingent, O.T.C.), T. McS. Wilson, W. M. Savery (from University of London Contingent, O.T.C.).

TERRITORIAL FORCE.

To be acting Colonels while employed as Assistant Directors of Medical Services: Lieut.-Cols. C. T. Green, E. V. Gostling, A. M. McIntosh, C. H. Howkins, H. Collinson, J. Mackinnon, F. Kelly, W. R. Matthews, E. C. Montgomery-Smith, E. A. Wraith, R. Pickard, and J. Clay; Majors T. Kay, D. Rorie, H. Richardson, and C. H. Lindsay.

To be acting Lieutenant-Colonels while specially employed: Majors A. C. Goodwin, A. W. Moore, A. E. Kidd, J. Wood, R. Coffey, J. W. Bird, J. Gray, F. Whalley, T. Donovan, H. T. Samuel, J. Evans, T. P. Puddicombe, A. P. Swanson, and E. B. Bird (Brevet Lieut.-Col.); Capts. A. T. Falwasser, G. T. Willan, H. G. G. Mackenzie, J. Barkley, J. Bruce, J. Young, T. A. Green, and C. W. Eames.

To be acting Majors while specially employed: Capts. J. W. McIntosh, T. G. Buchanan, H. G. Magroth, R. Waterhouse, R. Phillips, J. Turtle, J. D. Fiddes, J. F. MacIntosh, T. H. Peyton, W. D. Sturrock, O. H. Williams, E. Knight, E. L. Rowse, W. C. Macaulay, A. C. F. Turner, A. A. Hingston, H. B. Sproat, H. J. Dunbar, G. P. D. Hawker, R. Eager, H. C. Adams, F. E. Stokes, J. W. Kemp, H. W. Bayly, A. Leggat, L. P. Harris, S. F. St.J. Steadman, J. Chalmers, S. English, E. L. D. Dewdney, E. W. Matthews, H. F. W. Boeddicker, R. O. Sibley, J. H. Wood, W. F. Corfield, A. S. M. Macgregor, R. Proudfoot, A. B. Sloan.

Lieut.-Col. E. J. Lawless, from T.F. Res., to be Lieutenant-Colonel.

Lieut.-Col. E. M. Callender, from General Hospital, to be Lieutenant-Colonel.

Lieut.-Cols. J. B. Butler, W. J. Jones, A. R. Meggy, and F. W. Hearn are retired, having attained the age limit, with permission to retain their rank and to wear the prescribed uniform.

Lieut.-Col. P. Mitchell is restored to the establishment.

Major (Brevet Lieut.-Col.) (temp. Lieut.-Col.) J. Smart relinquishes his temporary rank on ceasing to command a General Hospital.

Major (acting Lieut.-Col.) R. T. Hughes and Capts. (acting Majors) R. Proudfoot and F. R. Humphreys relinquish their acting rank on ceasing to be specially employed.

Major R. Griffith, Capt. (acting Major) W. D. Sturrock, and Capt. P. Moxey to be acting Lieutenant-Colonels whilst commanding a Field Ambulance.

Capt. (acting Major) R. S. Taylor, D.S.O., is granted precedence in his acting rank.

Capt. A. McGillivray to be Major.

Capt. J. B. Adams is seconded for service overseas.

Capt. (temp. Major) D. W. E. Jones is seconded whilst holding a temporary commission in the Army Medical Service.

Major (temp. Lieut.-Col.) J. M. G. Bremner relinquishes his temporary rank on ceasing to command a Field Ambulance.

Capt. (acting Lieut.-Col.) D. H. Weir to be Major and to retain acting rank of Lieutenant-Colonel.

Capt. T. Porter relinquishes his commission on account of ill-health and is granted the honorary rank of Captain.

Temporary Captains to be Captains: W. Fitzpatrick, J. Muir, W. H. Broad, R. R. Macnicol, G. Moore, C. E. Whitehead, J. H. Jones, F. Ward, J. S. Hudson, H. M. S. Turner, C. S Young, H. G. L. Allford, E. A. C. Fazan, C. C. Lavington, J. A. Mathers, A. G. Hendley, H. W. Bayly, R. Verel, H. Wade, A. Mowat, R. W. C. Macdonald, L. Colledge, G. H. Hunt, A. W. Nuthall, H. C. Adams, and J. Cook.

General List.—Capts. A. G. Hebblethwaite and O. W. D. Steel to be acting Lieutenant-Colonels whilst commanding a Field Ambulance.

Captains to be acting Majors whilst specially employed: H. R. Dive, P. S. Martin, T. W. H. Downes, B. Hughes, R. W. Swayne.

Lieut.-Col. E. B. Dowsett to be Assistant Director of Medical Services and to be acting Colonel whilst so employed.

Temp. Capt. (acting Major) G. E. St. C. Stockwell to be Major (temporary).

Capt. W. B. Marshall to be acting Major whilst specially employed, and to remain seconded.

Major C. A. Leedham-Green relinquishes his commission on account of ill-health, and is granted the honorary rank of Major.

Capt. G. White relinquishes his commission on account of ill-health, and is granted the honorary rank of Captain.

Lieuts. R. McKenzie and A. G. Yates to be Captains.

J. G. Seppelt and R. F. White to be Lieutenants.

TERRITORIAL FORCE RESERVE.

Capt. A. Burgess, from R.A.M.C., to be Captain.

ROYAL AIR FORCE.

Medical Branch.—Capt. H. A. Treadgold to be acting Major whilst employed as Major.

Capt. A. H. Todd to be acting Major whilst specially employed.

Granted temporary commissions as Captains: W. Lessey (late Capt. R.A.M.C.), G. Fehrsen, W. Lumley (late Capt., R.A.M.C.).

Granted temporary commissions as Lieutenants: R. H. Burns, M. Hyman, N. C. Cooper, S. R. E. Davies, J. Gorsky, K. D. F. Waters.

Dental Branch.—Granted temporary commissions as Lieutenants: R. S. H. Drabble, P. J. Proud, L. S. Kettlewell, G. J. Roberts.

INDIAN MEDICAL SERVICE.

The King has approved the promotion of the following officers:—Colonel to be Major-General: W. H. B. Robinson. Lieutenants to be Captains: J. B. de W. Molony, H. G. Alexander, O. Wilson, J. J. Liston, K. R. Batra, B. H. Singh, P. D. Chopra, O. R. Unger, I. D. Grant, M. M. Khan, S. N. Mukerji, H. E. Murray, A. N. Bose, J. Dow, A. S. Fry, J. G. J. Green, W. P. Hogg, R. L. Vance, J. H. G. White, H. M. Collins, G. B. Hanna, A. H. Brown, C. H. Heppenstall, E. Cotter, U. J. Bourke, D. R. Thomas, C. C. Mecredy, C. W. W. Baxter.

To be acting Lieutenant-Colonels while commanding Indian Cavalry Field Ambulances: Majors W. H. Cazaly, J. J. Urwin, E. C. Hodgson.

The King has approved the retirement of the following officers: Lieut.-Col. G. W. Jenney, in consequence of ill-health due to field service. Lieut.-Col. G. B. Irvine, C.B., in consequence of ill-health due to field service, and is granted the honorary rank of Colonel.

The services of Temp. Lieut. Gokal Prasad Tiwari are dispensed with in consequence of medical unfitness.

YEOVIL AND DISTRICT HOSPITAL.—£1954 have been received by the Mayor of Yeovil's Fund towards the cost of providing a new building for the Yeovil Hospital.

Medical News.

THE INFLUENZA EPIDEMIC.

A CIRCULAR notice has been sent by the Local Government Board to all sanitary authorities, calling their attention to the recent Memorandum issued by the Board on "Epidemic Catarrhs and Influenza," and pointing out the necessity of securing nursing assistance and hospital provision. The notice encloses a circular letter from Sir Arthur Newsholme to the medical officers of health, asking that systematic inquiries, to be embodied in a special report, should be made in accordance with a given schedule into the incidence of influenza in all localities.

The Principal Medical Officer of the Local Government Board also asks that statements should be added to these reports dealing with any administrative action taken by the sanitary authorities, any distribution of precautionary advice or closure of public entertainments or schools, any provision made for hospital or domiciliary treatment of patients, for bacteriological examination, or prophylaxis by vaccines.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Final Examination, held from Oct. 8th to 23rd, the following candidates were approved in the undermentioned subjects, but are not eligible for diplomas:—

Medicine.—Margarita Sargood Barfield, Royal Free; C. W. Bennett, St. Bart.'s; E. P. Brockman, Cambridge and St. Thomas's; C. H. Bubb, Guy's; Gladys Mary Cooksey, Birmingham; A. Innes Cox, Middlesex; J. C. Davies, St. Bart.'s; J. C. Dixey, Oxford and St. Bart.'s; T. H. Dobrashian, Univ. Coll.; A. A. Forty, Guy's; R. S. Foss, St. Thomas's; E. J. Gaffney, Guy's; F. A. Georger, Buffalo Univ.; A. C. Halliwell, Cambridge and St. Thomas's; W. H. Haupt, George Washington Univ.; A. M. Kazim, Univ. Coll.; W. Lambert, Middlesex; F. W. Lemarchant, St. Bart.'s; D. Livingston, Durham; L. Lyne, Guy's; A. V. R. Menon, Madras Med. Coll.; D. O'Donovan, Cork and Univ. Coll.; J. L. C. O'Flyn, St. George's; A. G. Ord, Guy's; D. R. Owen, Liverpool; W. Reikan, Manchester; R. W. Revell, Univ. Coll.; J. C. Russell, Cambridge and London; Mary Sylvia Stocks, St. Mary's; C. M. Strong, Manitoba Univ.; W. S. Sykes, Cambridge and St. Bart.'s; R. W. Warrick, Guy's; Mary Howarth Wild, Liverpool; R. B. H. Wyatt, Oxford and St. George's; H. B. Yates, St. George's; and F. Young, Guy's.

Midwifery.—A. F. Abbassi, Edinburgh; R. G. Addenbrooke, Birmingham; S. T. Barrett, Cambridge and Guy's; Grace Mary Beaven, St. George's; C. W. Bennett, St. Bart.'s; E. J. Bilcliffe, St. George's; Hilda Crichton Bowser, Royal Free; J. V. C. Braithwaite, Guy's; E. E. Carter, St. Thomas's; R. H. Clarke, Cambridge and St. Bart.'s; H. S. Cohen, London; H. N. W. Collins, King's Coll.; Gladys Mary Cooksey, Birmingham; Ursula Beatrice Cox, Royal Free and St. Mary's; E. A. L. Crichlow and R. G. Dansie, King's Coll.; F. P. de Caux, St. Bart.'s; C. Dunscombe, Cambridge and St. Bart.'s; D. N. Dutt, Univ. Coll.; Sylvia Victoria Elman, St. Mary's; T. G. Evans, St. Bart.'s; J. Freilich, Univ. Coll.; F. J. Good, London; C. Griffith-Jones, St. Bart.'s; H. W. Hardy, Charing Cross; W. G. Hay and G. O. Hume, Guy's; A. Ismail, St. Thomas's; F. W. Kemp, Charing Cross; Muriel Mercer Kenworthy, Liverpool and Royal Free; H. W. Kerfoot, McGill Univ.; C. A. Kirton, Univ. Coll.; P. B. Kittel, Cambridge and St. Bart.'s; P. Lloyd-Williams, St. Thomas's; N. J. Macdonald, Cambridge and St. Bart.'s; W. K. McKay, Guy's; C. F. McLean, Cambridge and St. Thomas's; Kathleen Harding Matthews, St. Mary's; Margaret Ombler Meek, Charing Cross; J. S. Moore, St. Thomas's; G. E. Morgan, Oxford and London; A. G. Ord, Guy's; Sigrid Letitia Sharpe Pearson and Norah Dorothy Pinkerton, Royal Free; A. M. Ramzy, St. Thomas's; Eleanor Margaret Reece, Royal Free; R. W. Revell, Univ. Coll.; A. H. Richards, St. Mary's; S. Rose and A. E. Sawday, Guy's; E. L. Sergeant, London; Sonia Straschun, St. Mary's; W. S. Sykes, Cambridge and St. Bart.'s; E. Tagoe, Cambridge and Univ. Coll.; C. J. Thomas, St. Thomas's; W. G. Tilleke, Cambridge and Univ. Coll.; A. H. Turton, Birmingham; H. W. C. Vines, Cambridge and St. Bart.'s; K. T. K. Wallington, Univ. Coll.; A. E. Ward, St. Thomas's; A. D. Weeden, Middlesex; Effie Adela Wharton, St. George's; E. C. Whitehall-Cooke, St. Thomas's; R. B. H. Wyatt, Oxford and St. George's; and H. B. Yates, St. George's.

Surgery.—A. R. Aufranc, Middlesex; P. Banbury, St. Thomas's; E. P. Brockman, Cambridge and St. Thomas's; J. H. Crosskey, Birmingham; L. Duble, Louvain and St. George's; F. A. Evans, Manchester; G. W. T. H. Fleming, Durham; L. E. Frazer, A. C. Halliwell, and A. T. Hawley, Cambridge and St. Thomas's; C. T. Helsham, Guy's; A. R. Hill, Middlesex; T. L. Hilller, Cambridge and St. Thomas's; F. G. Hobson, Oxford and St. Thomas's; C. H. S. Horwitz, Guy's; C. O. Hudson, Sheffield; G. L. Levin, Univ. Coll.; T. C. McKenzie, Birmingham; A. V. R. Menon, Madras Med. Coll.; G. T. Mody, Bombay and Bristol; D. R. Owen, Liverpool; F. L. Pickett, Cambridge and Manchester; Dorothy Priestley Priestley, Leeds; J. C. R. Richardson, London; F. G. Spear, Cambridge and St. Thomas's; S. R. Tattersall, St. Thomas's; H. W. C. Vines, Cambridge and St. Bart.'s; and D. E. Wijewardene, Cambridge and St. Thomas's.

CENTRAL MIDWIVES BOARD FOR IRELAND.—The Central Midwives Board for Ireland held its second meeting at the offices of the Local Government Board, Custom House, Dublin, on Oct. 31st, when the chairman, Dr. E. Coey Bigger, proposed the following vote of condolence:—

"We, the members of the Central Midwives Board for Ireland, assembled at this, our second, meeting desire to tender to Mrs. McCarron, and all the members of her family, our sincere sympathy with them in the untimely and tragic death of Alderman McCarron. His colleagues on this Board wish to place on record their expression of their grief at the passing from their midst of one who had earned the esteem of everyone with whom he had come in contact."

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—A clinical meeting of this society was held on Nov. 1st at the West London Hospital, when the following cases were shown:—Major McAdam Eccles: 1. Arterio-venous Aneurysm in a private of 23, a German bullet passing through the right popliteal space. After being a prisoner in Germany for 15 months he became interned in Switzerland, where the late Professor Theodor Kocher operated, removing the sac, the operation lasting about five hours. A well-marked bruit is still audible; a considerable enlargement of the right calf with some venous congestion is present. 2. Fibro-sarcoma of thigh in a girl of 19, who first noticed a lump in outer side of the *left* thigh four years ago. This gradually increased in size, when a portion was removed for microscopical investigation in March, 1918. Radical operation was refused, a large local operation being performed in July, 1918. There is now local recurrence and a secondary nodule in the *right* axillary border. The patient appeared in extremely good health, with fresh colour and not losing flesh. 3. "A Foot-Hand." This extremely rare condition shows a deformity of the left hand which appears somewhat like a foot; five "toes," a "great toe," and four smaller "toes" projecting from the end of a blunted upper limb. Radiograms showed perfect development of the bones of the forearm and carpus on the deformed side, the carpal bones in the distal row being fused.—Dr. Arthur Saunders: Arthritis under Phylacogen Treatment, showing considerable improvement in the metacarpal joints affected.—Mr. H. Tyrrell Gray: 1. Gigantism of Right Index and Middle Finger in a boy of 4. 2. Congenital Dislocation of both Hip-joints.—Dr. Rickard Lloyd: Ulcerated Leg Healed by Old-fashioned Methods within 20 days.—Mr. Bishop Harman: 1. Three Cases of Detached Retina. 2. Post-polar Cataract.

NATIONAL ASSOCIATION FOR THE PREVENTION OF INFANT MORTALITY.—Three lectures on the Feeding of Children will be given by Dr. Eric Pritchard at Dr. Williams's Library, Gordon-square, London, W.C., on Nov. 12th, 15th, and 26th, at 5.30 P.M. The fee is 2s. 6d. for the three lectures. Tickets from Miss Halford, secretary, at 4, Tavistock-square, London, W.C.1.

URBAN VITAL STATISTICS.

(Week ended Nov. 2nd, 1918.)

English and Welsh Towns.—In the 95 English and Welsh towns, with an aggregate civil population estimated at 16,500,000 persons, the annual rate of mortality, which had increased from 11·4 to 30·9 in the five preceding weeks, further rose to 43·0 per 1000. In London, with a population slightly exceeding 4,000,000 persons, the death-rate was 55·5, or 21·0 per 1000 above that recorded in the previous week; among the remaining towns the rates ranged from 8·8 in Carlisle, 11·0 in Stockton-on-Tees, and 12·2 in Warrington, to 75·2 in West Ham, 79·2 in East Ham, 79·5 in Oxford, 79·6 in Hull, 83·3 in Sheffield, and 88·6 in Leicester. The principal epidemic diseases caused 233 deaths, which corresponded to an annual rate of 0·7 per 1000, and included 80 from infantile diarrhœa, 54 from diphtheria, 34 from whooping-cough, 30 from scarlet fever, 29 from measles, and 6 from enteric fever. The deaths from influenza numbered 7412, against 1895 and 4482 in the two preceding weeks, and included 2458 in London, 468 in Sheffield, 269 in Leicester, 240 in West Ham, 220 in Hull, 194 in Leeds, 190 in Bristol, 170 in Liverpool, and 145 in Stoke-on-Trent. The 4285 deaths in London were the highest recorded in any week and were 524 in excess of the previous highest number registered during the influenza epidemic of 1892; of the 2458 deaths from influenza no fewer than 1369 related to persons aged 15-45 years, while in previous epidemics the highest mortality occurred at the more advanced ages. The 1201 cases of scarlet fever and 1166 of diphtheria under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital were 50 and 34 below the respective numbers remaining at the end of the previous week. The causes of 87 deaths in the 96 towns were uncertified, of which 12 were registered in London, 10 each in Leicester and Liverpool, and 7 in Birmingham.

Scotch Towns.—In the 16 largest Scotch towns, with an aggregate population estimated at nearly 2,500,000 persons, the annual rate of mortality, which had increased from 10·6 to 29·4 in the seven preceding weeks, further rose to 30·5 per 1000. Of the 1407 deaths from all causes, 66 were classified to influenza, which was also stated as a contributory cause in 499 deaths classified to other diseases; in the previous week these numbers were 57 and 457 respectively. The 570 deaths in Glasgow corresponded to an annual rate of 26·7 per 1000, and included 9 from diphtheria, 7 from whooping-cough, 2 from scarlet fever, and 1 each from enteric fever and infantile diarrhœa. The 226 deaths in Edinburgh were equal to a rate of 35·4 per 1000, and included 2 from diphtheria and 1 each from enteric fever, scarlet fever, whooping-cough, and infantile diarrhœa.

Irish Towns.—The 501 deaths in Dublin corresponded to an annual rate of 65·5, or 18·2 per 1000 above that recorded in the previous week, and included 250 from influenza, 2 from whooping-cough, and 1 from infantile diarrhœa. The 132 deaths in Belfast were equal to a rate of 17·5 per 1000, and included 2 from scarlet fever and 1 each from enteric fever and infantile diarrhœa.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Armistices with Austria and Turkey.

STATEMENTS made in the House of Commons concerning the armistices with Turkey and Austria, and the conditions under which those countries surrender, have been received with the utmost satisfaction. These events and the military and economic exhaustion of Germany point to the early collapse of the enemy on the Western front and to the acceptance of the Allies' terms. Preparations are meantime being made for a General Election at a very early date.

The New President of the Local Government Board.

Sir AUCKLAND GEDDES has succeeded Mr. HAYES FISHER as President of the Local Government Board, and he will continue also his duties as Minister of National Service. The main function of the Ministry of National Service being to obtain men for the Army, its importance diminishes as peace draws near. In that case Sir AUCKLAND GEDDES will have an increasing amount of time to devote to his new office, where important work awaits him. The housing problem has to be seriously tackled. It is also considered highly probable that one of the tasks to which Sir AUCKLAND GEDDES will set his hand is the advancement of the scheme for a Ministry of Health. A medical man, he has already proved his capacity as an administrator.

Ministries of Health Bill.

Dr. ADDISON, the Minister of Reconstruction, is responsible for the introduction of a Bill in the House of Commons "to establish a Ministry of Health and a Board of Health to exercise in England and Wales and in Scotland respectively powers with respect to health and local government and for purposes connected therewith." The measure will be printed, and contains the proposals of the Government on this important subject. At this stage of the session, of course, it will be impossible to carry any new legislation through except by general consent.

The Midwives Bill.

The House of Lords has passed the Midwives Bill.

HOUSE OF COMMONS.

WEDNESDAY, OCT. 30TH.

Influenza at the Crystal Palace.

ANSWERING Mr. CHANCELLOR, Dr. MACNAMARA (Secretary to the Admiralty) said: There have been 120 deaths among men at the Crystal Palace during the last six months—117 from pneumonia following influenza, 1 from cerebro-spinal meningitis, 1 from cerebral abscess, and 1 from Addison's disease. The average number of men stationed at the Crystal Palace is roughly about 5600. During the course of six months the number of men passing through the Crystal Palace would be much greater than that. The main, practically indeed the only, mortality during that period has been from an epidemic of influenza, which, I regret to say, affected over 1000 men. Of the 117 men who, unhappily, died from pneumonia following influenza, none were inoculated against influenza or pneumonia. Prior to the outbreak of influenza at the Crystal Palace the average daily sick-rate had been slightly less than 3 per cent. Though the building was not originally intended as a living place, it has been satisfactorily modified subsequently to its being taken over at the beginning of the war, and the health reports prior to the present outbreak of influenza do not point to any serious objection to its continuing to be used for the purpose for which it was acquired. A very recent sanitary inspection of the building has been made, as a result of which certain minor defects in ventilation are being remedied.

Influenza in Belfast Prison.

Replying to Mr. BYRNE, who asked for particulars regarding the epidemic of influenza in Belfast Prison, Mr. SAMUELS (Attorney-General for Ireland) said: Dr. MacCormack, the medical member of the Prisons Board, specially visited Belfast Prison in reference to the influenza epidemic. He reports that there are now under medical treatment for influenza 111 prisoners committed under the Defence of the Realm Regulations and 14 officers of the prison. There is no foundation for the allegation that the food is insufficient or of poor quality, or that the medical or nursing arrangements are unsatisfactory. Special treatment and diet are afforded to each patient, and the medical officer to the prison has authority to engage additional medical assistance and trained nursing staff and to order any extra articles of food or medicines that may be deemed necessary. The prison medical officer has already called to his assistance Dr. Tweedie, of Belfast, and Professor H. L. McKisack, M.D., as consultant. There is no reason to think that the prisoners are not receiving all proper care and medical treatment.

THURSDAY, OCT. 31ST.

Influenza in Belfast Prison.

IN answer to Mr. KING, who asked for information concerning the influenza epidemic in Belfast Prison, Mr. SAMUELS said: The most recent information is as follows:—The number of cases of influenza that have occurred is 118. Of these nine patients have been removed to extern hospitals on the recommendation of the medical officer of the prison. The large majority of the remaining cases are suffering from a mild type of the disease and satisfactory treatment for them is available in the prison. Medicines and special dietary have been prescribed where necessary in individual cases, and where special nursing is required the patient is removed to an extern hospital. The medical officer has already secured the assistance of two other medical men as well as of Professor McKisack, M.D., consultant, and there is no reason to think that the cases are not receiving all proper attention.

Venereal Disease and Regulation 40 D.

Mr. LEES SMITH asked the Home Secretary how many resolutions he had now received demanding the withdrawal of Regulation 40 D of the Defence of the Realm Act.—Sir G. CAVE answered: About 600 such resolutions have been received at the Home Office.

Mr. W. ANDERSON asked whether the right honourable gentleman was aware that Regulation 40 D of the Defence of the Realm Act had been condemned by the most representative conferences of women; whether his attention had been called to medical opinion; that the regulation had been discredited as a public health measure; and that the presence of infection could not be proved or disproved by examination; whether he was aware of the number of women against whom no charge could be established, who had nevertheless been arrested, imprisoned, and remanded for examination under this regulation; and whether the Government was now prepared to take steps to annul this regulation.—Sir G. CAVE said in reply: The question, which is one of extreme difficulty, is being considered by a strong committee upon which both sexes are represented, and the Government must await the result of their deliberations before taking action.

Mr. H. SAMUEL: Can my right honourable friend say when the report will appear?—Sir G. CAVE: I should think certainly next month. I hope so.

Training Limbless Men in Ireland.

In reply to Mr. MACCAW, Sir A. GRIFFITH-BOSCAWEN (Parliamentary Secretary to the Ministry of Pensions) said: Several schemes of training suitable for limbless men are in operation in the north of Ireland.

Major NEWMAN: Are there any similar institutions in the south of Ireland?—Sir A. GRIFFITH-BOSCAWEN: Yes; there are certain training schemes in the south of Ireland.

Medical Service of the Air Force.

Sir WATSON CHEYNE asked the Under Secretary to the Air Ministry whether the principles laid down in the Medical Advisory Committee's Report, 1917, were now being carried into practice and what progress had been made.—Major BAIRD: A reorganisation of the medical arrangements of the Royal Air Force is now being considered in connexion with the appointment of a successor to the medical administrator.

Mr. JOYNSON-HICKS: Does that mean that the Medical Administrative Committee which was established in consequence of my honourable friend's report has been done away with?—Major BAIRD: The committee under the new arrangement will not be administrative, but will carry out advisory functions.

Sir WATSON CHEYNE asked whether the medical administrator of the Air Service had resigned and, if so, why; and what arrangements were being made in regard to a successor?—Major BAIRD: The resignation of the medical administrator originated in a difference of opinion between himself and the Medical Administrative Committee in regard to their respective spheres of responsibility. The appointment of his successor will be made public at an early date.

Mr. JOYNSON-HICKS: Has this appointment been offered to any officer at present?—Major BAIRD: The appointment is under consideration and an announcement will be made.

Sir WATSON CHEYNE asked whether the Medical Administrative Committee had been dissolved and, if so, why.—Major BAIRD wrote in reply: Under a reorganisation of the medical arrangements of the Royal Air Force now under consideration the administrative functions of the Medical Administrative Committee will cease, and it will become purely advisory.

MONDAY, NOV. 4TH.

Discharged Tuberculous Soldiers.

In reply to Lord H. CAVENDISH-BENTINCK, Sir E. CORNWALL (who replied on behalf of the representative of the Ministry of Pensions) said: A scheme for the domiciliary visiting of discharged men suffering from tuberculosis has been under consideration by my department during the last six months and has now been settled in conjunction with the Local

Government Board and the National Health Insurance Commission. Sanction for the necessary expenditure was received on May 17th last, but no part of the expenditure has yet been incurred, nor, I understand, have any appointments been made. The Local Government Board will very shortly issue the necessary instructions to the local authorities concerned. I would add that the present scheme is an extension of the arrangements for visiting and after-care which are already being carried out by local authorities in many areas.

Artificial Limbs.

Answering General CROFT, who asked a question bearing on artificial limbs for soldiers, Sir E. CORNWALL said: Artificial limbs very seldom need renewal owing to the shrinking of the stump, new buckets only being necessary, but it is clearly more satisfactory to supply a second limb when shrinkage of the stump has taken place and in the interval to supply a provisional limb in case of emergency.

Treatment of Shell Shock.

Mr. WING asked the Under Secretary for War whether he would give the names and situation of the institutions provided by the War Office for the care and treatment of uncertifiable soldiers who had been mentally unhinged in consequence of the severity of the strain through which they had passed; how many purely mental cases were segregated in each institution; what was their occupation; how many had been discharged recovered during the present year; and in how many instances were these institutions run by lunacy staffs and presided over by mental specialists connected with lunacy organisations.—Mr. MACPHERSON replied: I presume my honourable friend is referring in the first part of his question to men suffering from shell shock and neurasthenia. No purely mental cases are segregated in any institution. The occupations of the men whilst in hospital are mainly agriculture and farm work. There are also indoor occupations, such as carpentry, and also recreation and amusement. It would take a considerable time and involve a large amount of labour to ascertain the number who have been discharged as recovered, and I hope my honourable friend will not press for this information. None of the institutions are run by lunacy staffs, but in three of them the administrator is a mental specialist. The following is the list of institutions referred to:—Maudsley Neurological Clearing Hospital, Denmark Hill, S.E.; Springfield War Hospital, Upper Tooting, S.W.; Red Cross Military Hospital, Maghull; Abram Peel War Hospital, Bradford; Ewell (County of London) War Hospital, Epsom; 1st Southern General Hospital (Monyhull Neurological Section), Birmingham; Glen Lomond War Hospital, Fife; Dunblane War Hospital, Perthshire; Seale Hayne Neurological Hospital, Newton Abbot, South Devon; Gateshead War Hospital, Stannington, Newcastle-on-Tyne; Neurological Section, 4th Southern General Hospital, Plymouth; Neurological Section, 2nd Western General Hospital, Brinnington, Stockport; East Preston Military Hospital, near Worthing; Neurological Section, King George V. Hospital, Dublin; and Ashhurst War Hospital, Littlemore, Oxford.

Medical Administrator of Air Force.

Major TERRELL asked the Under Secretary to the Air Ministry whether the Air Council or the Secretary of State had offered or proposed to offer the appointment of Medical Administrator of the Medical Air Services of the Air Force to an officer of the R.A.M.C. on the terms that he would, in the administration of the Air Force Medical Service, carry out the principles recommended by the Watson Cheyne Advisory Committee; whether such officer had accepted or refused to accept the appointment on such terms, and if such officer had refused to accept such appointment on such terms, what action did the Secretary of State or the Air Force Council intend to take in the matter, and would the Secretary of State assure the House that whoever was appointed would be required to carry out the said principles in the administration of the Air Force Medical Service.—Major BAIRD replied: The post of Medical Administrator has been offered to Colonel Fell, R.A.M.C. One of the conditions of the offer is that he will be guided by the principles laid down in the report of the Watson Cheyne Committee, subject to certain amendments as regards principles of administration.

Major TERRELL: Has he accepted or refused these terms?—Major BAIRD: Colonel Fell is at present engaged in visiting the stations of the R.A.F. We shall get his answer when he returns.

TUESDAY, NOV. 5TH.

Medical Research Committee and Influenza.

Mr. ROWNTREE asked the representative of the National Insurance Commissioners whether the Medical Research Committee of the National Insurance Commissioners had for some time past been undertaking important research work in connexion with influenza; whether the results of the research had been made public; and, if so, whether a full use was being made of the knowledge they had acquired.—Sir E. CORNWALL answered: Yes, Sir, the Medical Research Committee have been continuously engaged since the beginning of the first wave of the epidemic last spring upon special efforts in regard to the etiology and the prevention of influenza and its complications. They have collected and periodically published expert reports of observations from all quarters, and have organised special researches in regard to it. These efforts have been more restricted than would otherwise have been the case owing to the urgent needs of the Army for pathological and other investigations into numerous kinds of diseases and wound problems, in which the Committee have also been heavily engaged from the outbreak of the war until now. The Committee's activities in all these fields are fully set out in the annual reports to me, which are presented to Parliament and have a wide distribution amongst experts and the profession, for whom, of course, they are from their nature mainly useful. Their fourth report, which is now before me, will be published in a few days. In reply to the second part of the question I may say that in the first week of August the Committee sent to the medical newspapers for the information of the medical and health authorities a résumé of various important communications on the subject of influenza, including an indication of the likelihood of the onset of secondary waves of the epidemic in the autumn, which their inquiries led them to expect would be more severe in character than the primary wave of last spring. For that reason the Committee on that date publicly invited observations from experts at various centres with a view to the further organisation of coördinated work in the study of those secondary waves. The severity of the present epidemic now shows that that anticipation on the part of the Committee, which can be read in the *British Medical Journal* of August 10th, was all too fully correct, and that the Committee did its duty in giving the warning beforehand to the expert authorities. As regards the actual epidemic itself, the Committee have been continuously collecting expert information likely to be useful to the health authorities and the medical profession as to its nature and progress in Europe from the chief foreign sources, including much important work done during these months in Germany and Austria. This the Committee have periodically published in English, combined with the results of British observations in their monthly medical supplements, of which several thousand copies are regularly distributed amongst professional experts and put on sale, early copies being sent to the Medical Department of the Local Government Board and other Government departments concerned. My honourable friend should see especially the September, October, and November issues, of which I am sending him copies. As regards the practical side of the problem I should state that the Committee were strongly represented at the important conference of bacteriologists held at the War Office some weeks ago on the possibilities of utilising vaccines for the prevention or treatment of the prevailing forms of influenza amongst the troops, under the chairmanship of Sir William Leishman, Adviser in Pathology to the Army Medical Department, and also a member of the Medical Research Committee. The outcome of that discussion was issued to the medical press by Sir William Leishman, and it also appeared in the pamphlet issued by the Local Government Board on the subject. In addition to this the Committee's bacteriological department have been giving aid to the War Office in the steps which have been taken to prepare and provide protective vaccines against the dangerous complications of secondary infections amongst the troops, and the Committee's secretary concurrently made suggestions to the medical officer of the Local Government Board for analogous steps to be taken by that Board for the benefit of the civil population. In this connexion, and in reply to the third paragraph of the question, I must remind my honourable friend that it is not the duty of the Medical Research Committee to carry out the actual treatment or prevention of this disease, which is the province of the public health authorities, local and central, but to obtain new knowledge and valuable information in regard to it by special researches and otherwise, and to have this readily available to those health authorities for them to put to its proper practical uses for the benefit of the civil population. The earlier paragraphs of this reply will have shown, I hope, that the Committee have carried out their proper functions in this respect with considerable effectiveness, especially in view of the difficulties occasioned by the constant loss of trained researchers claimed for military service.

WEDNESDAY, NOV. 6TH.

Medical Women in Military Hospitals.

Sir P. MAGNUS asked the Under Secretary for War whether, having regard to the fact that women doctors serving in military hospitals discharged similar duties and received the same pay as men doctors, and were entitled to wear the Royal Army Medical Corps badge, he would take steps to

rectify the anomaly of their being refused even honorary commissions or to wear badges of rank which would be helpful to them in maintaining discipline; and whether he could arrange that they obtained equivalent relief from income-tax as was granted to men doctors under the service rate.—Mr. MACPHERSON replied: I have been into this question very thoroughly, and I find that it is legally impossible to grant commissions in the Army to women. Legislation would be necessary. I should be glad to consider the granting of marks of distinction among themselves.

Sir P. MAGNUS: Has the right honourable gentleman any hope of being able to introduce the necessary legislation this session? Would the marks of distinction which he proposes be such as to enable these medical women to maintain the necessary discipline in order to carry out the work which they have to do?—Mr. MACPHERSON: As to legislation I will consult the Chancellor of the Exchequer. In regard to marks of distinction I am strongly opposed to the utilisation of the present Army marks of distinction. I would prefer marks of distinction to take the form of those which are given to administrators and directors of certain Women's Corps.

Mr. CURRIE: Will the right honourable gentleman answer the last part of the question as to relief from income?—Mr. MACPHERSON: I think I have already informed my honourable friend privately that that is purely a question for the Treasury.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.
THURSDAY, Nov. 14th.—Papers:—Mr. A. Mallock: Sounds produced by Drops falling on Water.—Mr. G. H. Hardy and Mr. S. Ramanujan: On the Coefficients in the Expansions of Certain Modular Functions.—Hon. R. J. Strutt: The Light scattered by Gases—its Polarisation and Intensity.—Dr. F. Horton and Ann C. Davies: An Investigation of the Ionizing Power of the Positive Ions from a Glowing Tantalum Filament in Helium (communicated by Mr. C. T. R. Wilson).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.1.
Wednesday, Nov. 13th.
GENERAL MEETING OF FELLOWS: at 4.30 P.M.
Presentation of the Diploma of Honorary Fellowship to Sir Alfred Keogh, G.C.B. (late Director-General of the Army Medical Service).
Discussion:
On "Influenza, with particular reference to the Epidemiology, Pathology, Clinical Aspects, and Complications," to be opened by Sir Arthur Newsholme, K.C.B., M.D.

MEETINGS OF SECTIONS.
Thursday, Nov. 14th.
NEUROLOGY (Hon. Secretaries—C. M. Hinds Howell, E. G. Fearnsides): at 8.30 P.M.
Presidential Address:
Dr. Henry Head, F.R.S.: Some Principles of Neurology.
Friday, Nov. 15th.
OTOLOGY (Hon. Secretaries—J. F. O'Malley, H. Buckland Jones): at 5 P.M.
Cases will be shown by—
Mr. Stuart-Low, Mr. Hunter Tod, Mr. Mollison, Dr. Dan McKenzie, and others.
ELECTRO-THERAPEUTICS
CLINICAL
MEDICINE
SURGERY: at 8.30 P.M.
On the invitation of the Section of Electro-Therapeutics a Joint Meeting of the above Sections will be held when a paper will be read by—
Dr. E. I. Spriggs on "The Radiography of the Vermiform Appendix" (illustrated by a number of lantern slides and drawings by Mr. Marxer).

MEDICAL SOCIETY OF LONDON, 11, Chandos-st., Cavendish-sq., W.
MONDAY, Nov. 11th.—8.30 P.M., Discussion on Reconstruction and the Practice of Medicine (introduced by Col. H. J. Waring, R.A.M.C.T.)

SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.
FRIDAY, Nov. 15th.—5.30 P.M., Paper:—Lt.-Col. A. Balfour, C.B., C.M.G.: Sanitary and Insanitary Makeshifts in the Eastern War Areas.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Clinics each week-day at 2 P.M., Wednesday, Friday, and Saturday also at 10 A.M.
(Details of Post-Graduate Course were given in issue of Nov. 2nd.)

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Out-patients each day at 2.30 P.M.

THE THROAT HOSPITAL, Golden-square, W.
MONDAY, Nov. 11th.—5.15 P.M., Special Demonstration of Selected Cases.
THURSDAY.—5.15 P.M., Clinical Lecture.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, 49, Leicester-square, W.C.
TUESDAY, Nov. 12th.—4 P.M., Dr. J. L. Bunch: Itching Skin Diseases and their Treatment.
WEDNESDAY.—5 P.M., Dr. W. Griffith: Skin Diseases in the Army.
THURSDAY.—5 P.M., Chesterfield Lecture:—Dr. M. Dockrell: The Diagnosis and Treatment of the late Eruptions of Syphilis.

ROYAL INSTITUTE OF PUBLIC HEALTH, in the Lecture Hall of the Institute, 37, Russell-square, W.C.
Course of Lectures on Public Health Problems under War and After-war Conditions (each Lecture will be followed by a Discussion):—
WEDNESDAY, Nov. 13th.—4 P.M., Lecture VI.:—Miss Jane Walker, M.D.: The Tuberculous Soldier.

NATIONAL ASSOCIATION FOR THE PREVENTION OF INFANT MORTALITY, at Dr. William's Library, Gordon-square, W.C.
Three Lectures on the Feeding of Children:—
TUESDAY, Nov. 12th.—5.30 P.M., Lecture I.:—Dr. E. Pritchard: Some General Principles.
FRIDAY.—5.30 P.M., Lecture II.:—Dr. E. Pritchard: The Quality of the Food.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BROWN, R. DODS, M.D., has been appointed Medical Superintendent of the Aberdeen Royal Asylum.
COLEMAN, C. J., M.D. Cantab., Certifying Surgeon under the Factory and Workshop Acts for the Lincoln District of the county of Lincoln.
FORTESCUE-BRICKDALE, J. M., M.D. Oxf., Physician to the Bristol Royal Infirmary.
MARSDEN, W. H., L.R.C.P. & S. Edin., L.F.P.S. Glasg., Acting Medical Officer for the Bleadon District (Axbridge).
NEILD, NEWMAN, M.B. Vict., Physician to the Bristol General Hospital.
NIXON, J. H., M.D. Lond., Medical Officer for the Lacock District (Chippenham).

Vacancies.

For further information refer to the advertisement columns.
Birkenhead Borough Hospital.—Jun. H.S. £170.
Bristol Royal Infirmary.—H.P. and H.S. £120.
Chester Royal Infirmary.—H.S. £200.
Devonport, Royal Albert Hospital.—Res. H.S. £200.
Dorchester, Dorset County Council Education Committee.—School Dentist. £350.
Essex County.—M.O.H. £1000.
Glamorgan County Asylum, Bridgend.—Temp. Asst. M.O. £6 6s. p.wk.
Glasgow, Lightburn Joint Hospital, Shettleston.—Res. Phys. Sup. £300.
Guy's Hospital, S.E.—Female Clin. Asst. 1 guinea per attendance.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. £100.
Leeds City Infectious Diseases Hospital, Seacroft.—Asst. M.O. £300.
London Temperance Hospital, Hampstead-road, N.W.—Medical Registrar. 40 guineas.
Manchester County Asylum, Prestwich.—Locum Tenens. £7 7s. p.wk.
Manchester Education Committee.—Two Temp. Asst. M.O's. £400.
Norwich, Norfolk and Norwich Hospital.—H.P. and H.S. £400 each.
Perth, James Murray's Royal Asylum.—Phys.-Superintendent. £800.
Reading, Royal Berkshire Hospital.—H.P. £250.
Roll of Honour Hospital for Children, 688, Harrow-road, W.—Female Asst. P.
Royal Free Hospital, Gray's Inn-road, W.C.—Female H.S.
Salford Union Infirmary.—Third Res. Asst. M.O. £300.
Sheffield, East End Branch of the Children's Hospital.—H.S. £150.
Sheffield Royal Infirmary.—Two H.S.'s. £150.
Stoke-on-Trent County Borough.—Temp. Tuberc. Officer. £350.
Wallasey, Victoria Central Hospital.—Hon. Oph. S.
Wolverhampton and Staffordshire General Hospital.—H.S. £200. Also Sen. Student.
York City.—Temp. Tuberc. Officer. £500.
York City Asylum, Fulford.—Temp. Asst. M.O. £350.

THE Chief Inspector of Factories, Home Office, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Llanfair Caereinion, Montgomery, and at Ballyfeard, co. Cork.

Births, Marriages, and Deaths.

BIRTHS.

MANSFIELD.—On Oct. 30th, at Sevenoaks, the wife of Lieutenant P. A. Mansfield, R.A.M.C., of a son.
NICHOLSON.—On Nov. 2nd, at Blockley, the wife of Major C. Nicholson, R.A.M.C., of a daughter.

DEATHS.

DOWNIE.—On Oct. 29th, at a British general hospital abroad, of influenzal pneumonia, James Maitland Downie, B.A. Cantab., M.R.C.S. Eng., Captain, R.A.M.C., in his 26th year.
MEIKLEJOHN.—On Oct. 31st, at Holland-road, W., John William Sinclair Meiklejohn, M.D., Deputy Inspector-General of Hospitals and Fleets, R.N., aged 89.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

BOOKS, ETC., RECEIVED.

COMMITTEE OF ORGANISATION, VITH INTERNATIONAL DENTAL CONGRESS, 19, Hanover-square, London.
Transactions of the VIth International Dental Congress. 30s. net.

CRANTON, HEATH, London.
On the Brain. By T. S. Dowse, M.D. 5s.

MARLBOROUGH AND Co., London.
Italian Self-taught, Grammar with Key (Thimm's System). 2nd ed. By G. Dalla Vecchia and A. C. Panagulli. 5s. 6d.

MURRAY, JOHN, London.
Junior Course of Practical Zoology. By the late A. Milnes Marshall, M.D., and C. H. Hurst, Ph.D. Edited and Revised by F. W. Gamble, D.Sc. 12s.

SIMPKIN AND MARSHALL, London. JOHN WRIGHT, Bristol.
On the Nature of Things. By Hugh Woods, M.D.

SIMPKIN, MARSHALL, AND Co., London. WARREN AND Co., Winchester.
New Army Cookery Book. By MRS. W. A. Featherstone, Q.M.A.A.C. 1s. 3d.

THE BUILDER, LTD., 4, Catherine-street, London, W.C. 2.
Fuel Economy in Cooking Apparatus. By A. H. Barker, B.Sc. 1s. 6d.

M.—Mr. J. B. Macalpine, Manchester; Lt.-Col. J. N. MacLeod, G.M.G., C.I.E.; Dr. J. C. McKerrow, Lond.; Mr. F. T. Mullett, Cambridge; Mr. J. McLaggan, Torphins.

N.—National Association for the Prevention of Consumption, Lond.; Capt. T. P. Noble, R.A.M.C.

P.—Dr. W. T. G. Pugh, Carshalton; Miss M. E. Pearson, Lond.; Dr. H. A. Powell, Lond.; Mrs. G. W. Pocock, Portlahead.

R.—Royal Institution, Lond.; Dr. Rivers, Worsboro' Dale; Royal Free Hospital, Lond., Sec. of; Dr. W. M. Richards; Royal College of Surgeons of England, President and Council of; Miss J. Ross, Glasgow; Royal Society, Lond.; Dr. R. R. Rentoul, Liverpool.

S.—Dr. A. Savill, Lond.; Societat de Biologia de Barcelona; Dr. E. I. Spriggs, Banff; *The Sphere*, Lond., Editor of; Society of Tropical Medicine and Hygiene; Mr. J. T. Segrue, Lond.; Surg.-Lieut.; Mr. W. A. Sands, New York; The Stratford Company, Boston; Mr. W. J. Stevenson, Lond.; Dr. R. V. Solly, Exeter; Capt. V. E. Sorapure, R.A.M.C.; Sir Walter M. Fletcher, K.B.E., Lond.

T.—Mr. B. C. Tillett, Lond.; Lt.-Col. C. N. Thornton, S.A.M.C.; Dr. J. Tatham, Oxted; Mr. F. Triefus, Lond.; Tasmania, Agent-General for, Lond.

U.—United Water Softeners, Ltd., Lond.

V.—Capt. A. B. Vine, R.A.M.C.

W.—Dr. L. B. Weatherly, Bournemouth; Dr. C. H. Whiteford, Plymouth; Dr. T. Wilson, Birmingham; Dr. W. H. Wynn, Birmingham.

Communications relating to editorial business should be addressed exclusively to The Editor of THE LANCET, 423, Strand, London, W.C. 2.

A WILTSHIRE CENTENARIAN.—Major J. Awdry, V.D., of The Paddock, Chippenham, recently celebrated the 100th anniversary of his birthday.

LITERARY INTELLIGENCE.—Dr. Ernest Muir, of the Mission Hospital, Kalna, has written a book with the object of placing within the reach of the medical practitioner in small towns and villages in India a guide to the diagnosis and treatment of kala-azar, which in some parts of India is very prevalent. Sir Leonard Rogers has furnished a foreword to the work.—Messrs. Cassell and Co. announce the forthcoming appearance of a sixth edition of Luff and Candy's "Manual of Chemistry," revised and enlarged by Mr. Candy.

Notes, Short Comments, and Answers to Correspondents.

THE MENACE OF VENEREAL DISEASE.

THE fourth lecture on "Public Health Problems under War and After War Conditions," dealing with the prevention and abortive treatment of venereal disease, was delivered at the Royal Institute of Public Health on Oct. 30th by Lieutenant-Colonel L. W. Harrison, D.S.O. Sir George H. Makins, President of the Royal College of Surgeons of England, who presided, introduced the lecturer by stating that the present war might be followed by a huge increase in venereal disease throughout the country, and unless it was combated the result to the nation would be disastrous. Two classes of women, amateur and professional, said Lieutenant-Colonel Harrison, infected our soldiers, and, generally speaking, two-thirds of the cases of venereal disease dealt with among soldiers was due to infection by the amateurs. After the war the burden of combating the disease would fall chiefly on the civilian community. More had been done in the matter of education in this connexion by a few devoted workers in the four years of the war than during the past 400 years, but ignorance was still appalling, and it was necessary that the public should know how to protect itself against the disease. Syphilis comprised only about one-quarter of venereal disease, and although we had admirable remedies against it the long periods of treatment under which the patient must be under observation made treatment costly. The successful management of gonorrhœa was immensely more difficult than that of syphilis, though, unfortunately, a large number of doctors still looked upon it as a light matter. It was one of the most difficult tasks in medicine to clear the genital passage from the gonococcus. From a medical point of view the prevention of venereal disease was as easy as cure was difficult. With regard to soldiers, experiences at Aldershot had shown that the admission-rate for venereal diseases could be materially lowered by providing healthy distractions. In 1885 the ratio per 1000 per annum of admissions for venereal disease was very high, but it gradually decreased until the period of the South African War, when there was a relapse. From then onward to 1913 a decrease was again shown. This the lecturer considered to be due to the fact that Aldershot had been made a model home for the soldier, who need not leave barracks in order to find amusements and recreation of congenial kinds. From this he argued that something more might be done in providing healthy distractions for civilian working men. If workmen's clubs were made something better than pot-houses, and places provided where men could be really comfortable in their leisure hours, it would not only tend to reduce the spread of venereal disease, but increase efficiency, and in terms of pounds, shillings, and pence would be profitable. With regard to segregation of women, the proper inspection of women on a large scale was impracticable. The best plan for dealing with prostitutes was to act on the assumption that all were diseased and teach them how to avoid infecting the men. But if we could make the prostitute safe, there remained still the perfectly hopeless class of amateurs to deal with. The greatest hope lay in breaking the chain at the male end by prophylactic treatment, but disinfection must be carried out soon after connexion. He advocated the appointment of subsidiary centres for treatment after instruction at the central clinics, but whatever arrangements were made for the treatment of venereal diseases it was necessary to have the coöperation of the public, and it was the duty of the medical profession to secure that coöperation by education.

Colonel Walker testified to the excellent results of prophylactic treatment on the American soldier in France.

Sir Thomas Barlow said that the moral side and medical side of the question were not incompatible, and so long as we could use prophylactic measures, not as an encouragement to men to expose themselves, but as a means of helping them after they had gone astray, it was the imperative duty of the medical profession to do so.

Sir George Makins contended that the question of continence was no more than abstention from alcohol or anything else, and we ought not to make it easier for people to be incontinent.

The lecturer, in reply to questions, did not consider that prophylactic treatment encouraged sexuality. We were dealing with an implacable foe, and it was no more unchristian to use the methods indicated than to fight on Sunday or use a gas against another implacable foe. Colonel Harrison also said that teetotalers formed a large proportion of venereal patients, and in one hospital 34 per cent. of venereal cases up to date proved to be total abstainers. He could not explain the circumstance, but thought it might be due to the fact that the abstainers

were bored by the distractions provided for them. Colonel Walker agreed that many teetotalers were infected; he could not explain the matter, but admitted, on the other hand, that alcohol and the prostitute went hand-in-hand.

THE ROYAL EARLSWOOD INSTITUTION FOR MENTAL DEFECTIVES.

WE have recently received the seventy-first annual report of this institution, formerly known as the Earlswood Asylum. In a spirit of war economy the report for 1917 is severely curtailed, and we regret the absence of the statement contributed by the medical superintendent (Dr. C. Caldecott), which has usually formed an interesting supplement to the report of the board of management. It is unsatisfactory to learn from the latter that this old-established charity has suffered from a falling-off of annual subscriptions owing to war conditions, which have also led to a serious increase of expenditure in food, clothing, and establishment charges. Consequently the board have had to resort to bankers' loans amounting to £15,000. Payments (both large and small) received for patients furnished during 1917, apart from charitable contributions, over £22,000, a sum which would meet about half of the year's total expenditure. It appears from two paragraphs concluding the report that the general health of the patients had been well maintained in spite of dietary difficulties and a mild epidemic of measles extending to 144 cases. An unusual number of patients of advanced years and lengthened residence had died during 1917.

Appended statistical tables furnish some items of medical interest. During 1917, 43 cases were admitted or readmitted, 34 were discharged, and 39 had died. The average number resident had been 478—318 males, 160 females—and calculated on this number the percentage of deaths for 1917 amounted to 8·15, a ratio greatly in excess of previous records of mortality during the 70 years' existence of the institution. A table showing the certified causes of death attributes 17 of the 39 deaths to tuberculous affections and 3 to epilepsy; and we gather that amongst the deaths recorded were those of 3 sexagenarians and of 3 septuagenarians, the oldest being a man of 77. The comparatively large number of elderly cases has involved a higher death-rate.

A PIONEER OF INFANT WELFARE.

MUCH suffering has been mitigated by the benevolent work of Mr. Nathan Straus, of the New York Pasteurised Milk Laboratories, who has been a pioneer in the saving of infant life by distributing at his own expense pasteurised milk to the poor of New York City, while in other generous ways he has served the poor and homeless. His activities in ministering to distress in the Eastern sphere of war have prompted the Rev. Rabbi Roth, on the occasion of the Jewish New Year, to send through the American Consul-General in Cairo the following telegram, which has been acknowledged by Mr. Lansing, of the State Department, Washington:—

> For Nathan Straus.—In the name of thousands saved from starvation by your institution, I wish you and your family happy New Year and prosperous future. May God bless you.

Besides establishing a soup kitchen two years before the war, Mr. Straus has since started a Health Bureau and Pasteur Institute in Jerusalem, the activities of which institution extend throughout Palestine, and which has been used by the authorities to check the spread of cholera and other infectious diseases.

EASY CAR-STARTING IN COLD WEATHER.

Mr. J. F. Rey, M.R.C.S., writes from Bognor that, like many others who do not possess a heated garage, he has for years experienced great trouble in starting his car in frosty weather. He continues:—

> "Having reached the limit of my patience with the possession of a self-starter car, and determined not to misuse the accumulators, I sat down and devoted a quarter of an hour to thinking out the problem, and, to cut a long story short, proceeded to put my theory into practice. Triumphantly carrying out a kettleful of boiling water (about a pint), at first I cautiously poured the contents over the induction pipes, carburettor, and spraying chamber, putting previously a small tin cap over the hole on top of the float chamber. I was gratified that at the first turn of the handle, or the first push of the self-starter, the engine started as though on a hot summer's day. One need not be afraid of pouring boiling water over the induction apparatus, as these are all hollow tubes of metal and no harm can come to them, nor is there any fear of water getting into the carburettor with the engine at rest and a small plug or plate placed over the small hole of the float chamber. I am certain that this simple method will save motorists untold misery."

PAYING PATIENTS AND THE WEST OF ENGLAND EYE INFIRMARY, EXETER.

THE annual meeting of the subscribers to this institution was recently held. The medical report stated that 2724 patients had been treated during the past year. The daily average number of in-patients was 16. It was decided that patients who had small means and were willing to pay towards the cost of treatment should be charged a fee, the amount being arranged between the committee and the medical officer in charge of the case.

ANTENATAL CARE IN THE U.S.A.

THE birth-rate in the United States has not decreased to an appreciable degree so far during the war, while the work of saving babies is making progress. A measure likely to help much in reducing infant mortality from congenital causes has been recently introduced into the United States Senate by Senator Robinson, entitled "A Bill to Encourage Instruction in the Hygiene of Maternity and Infancy, and to Extend Proper Care for Maternity and Infancy; to Provide for Coöperation with the States in the Promotion of Such Instruction and Care in Rural Districts; to Appropriate Money and Regulate its Expenditure, and for Other Purposes." This Bill provides for subsidising the States up to a sum of $10,000 a year each, with the provision of an additional subsidy, provided the State raises an equal amount of money to be used for the employment of rural nurses for antenatal instruction and maternity aid.

PREVALENT DISEASES IN DOMESTIC ANIMALS.

THE annual report of the Chief Veterinary Officer for the year 1917, which has just been issued (H.M. Stationery Office, price 2*d*.), deals with four diseases affecting horses and cattle which have been of special importance during the year. 10,261 suspected outbreaks of swine fever were reported, but only 2104, or a little more than one-fifth, of the outbreaks confirmed. Evidently pig diseases are still very imperfectly understood, and there is a tendency among breeders to class all affections of the pig as swine fever. An American practitioner recently stated that 40 per cent. of the average veterinary practice in Iowa was swine practice and he made a particularly strong plea for practitioners to get away from the belief prevalent some years ago that a sick hog necessarily had cholera.

Results are compared in the serum and non-serum outbreaks. Roughly, about 23 per cent. more pigs were freed from swine fever by the serum method than without it. This represents a good saving, and is encouraging. Where pigs are ripe and not breeding stock it is useful to slaughter and salve the pigs exposed to infection. From observations made it appears that large numbers of affected pigs were killed for food, and no doubt little harm and much economy were effected by the procedure. There were 25 outbreaks of glanders, a decrease of 19 as compared with 1916—469 horses and 1 mule were on infected premises, and 63 animals, including the mule, were destroyed, being found infected clinically or by means of the test. By post-mortems in 58 cases the presence of glanders was confirmed. Cattle and pigs furnished the majority of the cases of anthrax, and 203 out of 343 cases on previously clean premises were ascribed to the use of imported feeding stuffs. In 26 cases the disease was found in carcasses that had reached slaughter-houses or knackers' premises—a rather disturbing fact. Eight human beings developed anthrax as a result of dealing with the carcasses.

The double dipping of sheep seems to have reduced the trouble from sheep-scab, but Scottish sheep still seem largely responsible for outbreaks of the disease in England. As was only to be expected under war conditions and present regulations, parasitic mange in horses has shown a greater tendency to spread. Our experience has been that it has increased in all animals, including the cat, pig, goat, and dog. The scarcity of nutritious food is a factor in the matter.

"BLOW-HARD," OR METHYLATED SPIRIT.

IN reference to an ex-soldier charged in the Belfast custody court on Oct. 26th with being drunk from taking methylated spirit, the resident magistrate, Mr. Garrett Nagle, said that 9 out of 10 cases of drunkenness brought before him were against people who had taken methylated spirit in the form called, "blow-hard." He said it was an extraordinary circumstance that while methylated spirit was so difficult to purchase for domestic purposes men seemed to get drunk on it without any difficulty. The usual way the methylated spirit is taken is to mix a wineglassful with a pint of porter, and this mixture is really the "blow-hard," and is a cheap intoxicant.

The Laboratory of the Royal College of Physicians, Edinburgh, is preparing the mixed vaccine of *B. influenzæ*, *pneumococcus* and streptococcus recommended by the War Office conference. The supply can be obtained through Messrs. Duncan, Flockhart, and Co., 104, Holyrood-road, Edinburgh.

AT a recent meeting of the governors of the Royal Devon and Exeter Hospital, Exeter, Sir E. Chaning Wills, the President, stated that there were 100 patients waiting admission. He added that as an enlargement of the hospital was necessary, if the Government would release materials and sanction the scheme, Lady Wills and himself would give a substantial sum towards the appeal for financial support which the committee would make.

Presidential Address
ON
SOME PRINCIPLES OF NEUROLOGY.

Delivered before the Neurological Section of the Royal Society of Medicine,

BY HENRY HEAD, M.D. CANTAB., F.R.S.,
PHYSICIAN TO THE LONDON HOSPITAL.

LADIES AND GENTLEMEN,—It is exactly 26 years since I had the honour of reading my first paper, on Pain in Visceral Disease, before the Neurological Society. Looking back over a quarter of a century, it seemed to me that I might employ my Presidential Address most profitably by considering certain principles which underlie the standpoint of neurology to-day. I am not going to weary you with an historical epitome. In this quarter of a century there have been no startling discoveries; but I believe that to-day the outlook of the younger generation is fundamentally different from that in which we were brought up, and I shall attempt to indicate the direction in which it seems to me the science of neurology is moving.

SATISFACTION WITH WORDS IN THE PAST.

The cataclysmic events of the last four years have shaken men's belief in the old order, and medicine has not escaped the universal demand for a restatement of current values. The young are looking to us to enunciate the principles on which our teaching is founded. They are not disposed to accept without criticism conventional explanations. They regard with scepticism the statements, current in text-books, that the manifestations of an epileptic convulsion are the expression of "irritation of the cortical centres," or that aphasia is explained by "the destruction of visual, auditory, or motor images." Their curiosity is no longer satisfied by attributing the sensory changes, caused by a peripheral nerve injury, to a "paræsthesia" or "hypo-æsthesia." And, indeed, words of this order are but anodynes to the conscience. They explain nothing; they serve only to put to sleep the salutary feeling that further investigation is necessary.

Satisfaction with words, that are in many cases nothing more than a restatement of the problem in bastard Latin and Greek, was one of the most remarkable characteristics of the last quarter of a century. No better example could be found than the misuse of the word "toxæmia." We are assured that certain diseases are due to this cause; but, although we know much about the pathological changes in the central nervous system, the symptoms they produce, and the course of the disease, the "toxin" is purely hypothetical. Everywhere we find this remarkable tendency to explain the known by the unknown.

Now, every student of Natural Science should retain something of the simplicity of the child. You all remember the story of the emperor and his new clothes. Two weavers asserted that they had woven a cloth of extreme beauty and fineness; it had, however, one unusual characteristic: it was invisible to those who were stupid or unworthy of the post they held. Neither the emperor nor his courtiers could, it is true, see the stuff, but each was anxious not to betray himself, and all were loud in its praises. Royal robes were made of this wonderful material, but as the procession wound through the streets a child called out, "Why, he has nothing on"; and the child's saying passed from mouth to mouth among the crowd. So the young to-day are calling to us to recognise that many of the terms we use so glibly mean nothing. They do not cover the nakedness of our explanations.

CONCEPTION OF SYPHILIS OF CENTRAL NERVOUS SYSTEM.

This satisfaction with names is apparent in our conceptions of disease. No better example could be found than the customary attitude of clinicians towards syphilis of the central nervous system.

Tabes dorsalis and general paralysis of the insane are thus spoken of as "diseases." In reality, there are two factors only in the morbid manifestations produced by syphilis of the nervous system, the character of the infective activity and the site of its anatomical incidence. The *Spirochæta pallida* may attack almost any structure, and the "disease" expresses the functions of the tissues affected. Tabes dorsalis is a convenient term to express the fact that the principal focus of the destructive process lies in the posterior columns, and "general paralysis" simply indicates that it has fallen mainly on the higher cerebral centres. Year by year the line, once so finely drawn between tabes dorsalis and dementia paralytica, grew fainter as the identity of the pathological process underlying the two conditions was recognised. With the invention of the term "tabo-paresis" the boundaries between the two diseases fell. We now know that any nervous function, from the lowest reflexes to the highest intellectual activities, may be affected in consequence of syphilitic infection of the nervous system; and it is only by arbitrary selection that these diverse signs and symptoms can be erected into "diseases."

Then, again, "parasyphilis" was supposed to be the manifestation of a process, syphilitic in origin, but not strictly syphilitic in nature. We now believe that "parasyphilis" is nothing more than an anaphylactic reaction in the tissues of the central nervous system, which have been rendered hypersensitive in accordance with their peculiar lymphatic supply. "Parasyphilis" does not differ from "chronic cerebral syphilis" in any essential pathological particular. It is merely a similar reaction in a different tissue. No better example could be given of the law that, in morbid conditions of the nervous system, the form assumed by the disease is determined by the site of the destruction, whilst the course it runs is dependent on the natural history of the pathological process.

CHANGED ATTITUDE OF THE NEUROLOGIST.

During the last few years the attitude of the neurologist has undergone a subtle change, not only to disease, but also to its general effect upon the patient. At one time everyone was seeking for a sign or a syndrome. Happy the man who could discover a new reflex; it did not matter that he left it unexplained and failed to correlate it with other ancillary functions. It was a "fact," and to it his name was attached.

But the discovery of such a phenomenon is nothing more than the statement of the terms of the problem awaiting solution. To find its explanation we must look to the behaviour of the nervous system as a whole and observe how its reactions are changed. In many cases this leads to the consideration of phenomena which would have been thought frivolous by the older generation. Take, for example, the importance attached to the patient's account of his own sensations, or the diagnostic value now attributed to certain dreams.

In 1901 I described certain mental changes associated with disease of the heart and lungs, and showed that they formed another aspect of referred visceral pain. This work fell dead. For those who were interested in morbid conditions of the internal organs cared nothing for changes in the mental state of the patient; on the other hand, the alienists denied the facts, because of the remoteness of asylum life from the conditions of hospital experience. They made no effort to discover, whether such remarkable examples of the dependence of mental states on disturbances of bodily functions were really open to their investigation. To-day, however, this work is falling into its place as a small contribution to the relation of body and mind.

Interest in the functions of the nervous system as revealed by disease is steadily growing. The English school has always been essentially physiological, from the days of Marshall Hall onwards; but this growing attention to function is mainly due to the teaching of Hughlings Jackson. He sprang from the physiologists of the middle of the last century, and was deeply imbued with the principle of evolution not only of structure, but of function. But his contemporaries became increasingly obsessed with anatomical and topographical details. As years passed by, the teaching of the day moved away from Jackson's conception of an evolution of function, still demonstrable in the activities of the nervous system. Finally, his doctrines were scarcely comprehensible to those of us who were brought into daily contact with him in the wards, seduced, as we were, by the glib generalities of more popular teachers. But, when we came to think for ourselves, we found that his conception of a functional hierarchy, in which one form of activity was dominated by another standing higher in the evolutionary scale, explained much that was otherwise inexplicable in the

phenomena of nervous disease. This swing back to the physiological aspect was quickened by the exquisite researches of Sherrington, and the issue of his "Integrative Action of the Nervous System" in 1906 marks an epoch in the progress of neurology.

Integrative Action of the Nervous System.

We then began to appreciate that the existence of the central nervous system was due to the necessity of producing coherent action in a plurisegmental organism. Out of the primitive materials at her disposal, Nature was forced to develop a mechanism capable of integrating the physiological forces evoked by relations with the external world. As the animal rose in the evolutionary scale, the functions required of the nervous system became more and more complex, and out of the anatomical structures of a lower organism had to be developed machinery capable of exercising these higher activities.

This was only possible by integrating the crude physiological processes excited by external stimulation or arising in response to the action of internal forces. A prick excites a universal tendency to withdraw the part exposed to stimulation; it can also evoke a highly organised movement, such as the scratch reflex, capable of removing the noxious object.

But such reflexes are pre-ordained and admit of no choice. It became necessary, therefore, to develop a controlling mechanism that would permit the animal either to attack the stimulus locally or to evade its action by flight. Finally, with the development of the neopallium, was given the power of voluntary choice; the reaction was no longer unconscious, but could be preceded by a definite act of discrimination.

This adaptation to a clearly determined end demands a multitude of adjustments, and such integration is the business of the central nervous system. It can only be carried out by utilising, in a modified form, functions originally developed for a somewhat different purpose. Thus, the withdrawal movement, which forms the basic reaction to pricking the sole of the foot, is controlled by higher centres in the mid-brain and forms the flexor aspect of the stepping reflex. But, when this higher influence is completely removed, as, for example, by total transection of the spinal cord, the lower reflex becomes manifested in its primitive form as a pure movement of withdrawal, accompanied by evacuation of the bladder and rectum.

Afferent Impulses from the Viscera.

Structure is anchored in the past, and expresses in its anatomical dispositions functions which have passed away. Many of them have been carried up to centres of more recent origin, whilst others are exercised normally, in a refined form, under the control of those higher in the evolutionary scale. But nothing remains in its old form, unless it is of utility to the organism under some possible conjunction of circumstances.

Thus, the afferent impulses from the viscera do not normally enter consciousness. The eupeptic knows nothing of the processes of digestion, beyond a certain gentle sense of well-being. But, under abnormal conditions, afferent impressions from the internal organs are capable of arousing pain and discomfort. When this occurs, one form of this sensory disturbance is referred to the superficial structures of the body and is associated with areas of tenderness corresponding to a segmental arrangement of the central nervous system. This is not a "hyperæsthesia," but a tendency to react more violently to any stimulus capable of evoking discomfort. The threshold is not materially lowered, but the vehemence of the response is greatly increased.

Now, this over-reaction is associated with reflexes which still reveal their old defensive character. As an answer to visceral pain, the abdominal muscles become tonically contracted and the leg is drawn up on the affected side. The sufferer is forced to creep into some sheltered place and to lie curled up, till he either dies or recovers. All capacity to move as a whole is abolished; the reactions of the part affected now dominate the activity of the complete animal. Visceral reflexes of this order are antagonistic to general movements, and this is expressed not only in muscular immobility, but in the mental attitude which accompanies visceral pain.

Pain is the oldest defensive reaction and potentially painful stimuli are the basis of all primitive reflexes. It is, therefore, of importance for higher development that these impulses should be rendered less effective in favour of those impressions which lead to a more general and discriminative response. But, although they are controlled and even abolished, the mechanism underlying the production of pain must remain in full physiological activity, ready to play its part, should occasion arise, in the defence of the body against noxious influences.

Control of Higher over Lower Nervous Centres.

The functions of the central nervous system are not a palimpsest, where a new text is written over an earlier manuscript, partly erased. The more primitive activities have been profoundly modified by the advent of the new centres, which utilise some of the faculties originally possessed by the older mechanism. In many cases, the higher function could not be exercised without the existence of these lower powers which it dominates and controls.

When, however, the higher mechanism is thrown out of action, the functions of the lower centres are free to exhibit their activity unchecked. Jackson insisted that the manifestations due to a lesion of the central nervous system must be considered from a negative and a positive aspect. Injury to the pyramidal system was shown negatively in the loss of the finer voluntary movements, but the activity of the lower centres, released from control, was evident in the spastic rigidity of the paralysed parts. In the same way removal of the control normally exercised by the cortex over the activity of the optic thalamus leads to the remarkable condition known as thalamic over-reaction;[1] all stimuli capable of evoking discomfort, and in some cases even pleasurable excitation, cause an exaggerated response on the affected half of the body. This is not due to "irritation"; it is due to release. It is the direct consequence of loss of that control normally exercised by the cortex over the activities of the optic thalamus. Once this control is removed by disease, the lower centre reacts unchecked to any stimulus capable of exciting a response.

It has been the custom to call upon a hypothetical "irritation" to explain all such positive manifestations of nervous energy. The violent flexor spasms and the outbursts of excessive sweating, which occur when the spinal cord is injured, have been attributed to this cause. In reality they are the expression of a diffuse and massive response to stimuli, applied to parts below the level of the lesion; they are manifestations of a primitive mode of reaction, due to removal of control from above. Invo untary movements in hemiplegia, automatic acts following an epileptic attack, the emotional utterances in aphasia are all examples of the same phenomenon.

The condition of sensibility during the protopathic stage of recovery from a peripheral nerve lesion is another instance of a primitive mode of reaction, released from control by the tardy restoration of the epicritic mechanism. Normally the massive "all or nothing" response of the more primitive system is held in check by the localised and discriminative sensations, due to excitation of the epicritic end-organs. But, when the one set of afferent impulses is permitted to play on the ultimate sensory centres unchecked by those arising in the higher mechanism, the response becomes massive and diffuse, and extensity becomes of greater import than intensity.

Importance of Scientific Principles in Neurology.

Had we applied Jackson's law, that the functions of the nervous system are integrated on evolutionary principles, neurology would not have made so many excursions into the wilderness. He taught us that a lesion of the cerebral cortex caused disorder of movement, not paralysis of the muscles. This lesson, however, was not applied to the other functions of the cortex. Much time was wasted on topographical localisation of various sensory centres before the nature had been determined of the functions exercised by the cortex. Now we know that, as far as somatic sensibility is concerned, the cortex is responsible for the appreciation of spacial relations, for the power of responding to different intensities of stimulation, and for the capacity to recognise similarity and difference in external objects brought into contact with the body. The cortical centres are not concerned with the crude appreciation of touch, pain, heat, and cold.

Such principles are not only of theoretical importance; they are perpetually thrust before the neurologist in his

[1] THE LANCET, 1912, i., 79.

daily work. Clinical diagnosis is a by-product of scientific investigation. It is impossible to expose every patient to laborious scientific examination, nor would it serve any useful purpose to do so; but the simple tests employed in the wards are valueless until they have been calibrated by more elaborate investigations. The man who says he can obtain all the information he wants, in cases of injury to peripheral nerve, by means of a pin and a piece of cotton-wool depends on someone else to teach him the significance of these empirical tests. They have no scientific value until the data they yield are correlated with results reached by methods capable of measurement.

The charm of neurology, above all other branches of practical medicine, lies in the way it forces us into daily contact with principles. A knowledge of the structure and functions of the nervous system is necessary to explain the simplest phenomena of disease, and this can be only attained by thinking scientifically.

CONSIDERATION OF LEADING PRINCIPLES.

Let us then consider some of the leading principles which the candidate of the future must master in the course of his initiation.

Effect of Lesion on Complex and Simple Functions.

(1) When any level[2] of activity is attacked the most complex functions, and those which have appeared most recently, are the first to suffer. They are also disturbed to a greater degree and to a wider extent than those which are simpler or more inevitable in their expression.

An excellent example of this rule is seen in the effect of a lesion of the sensory cortex on the appreciation of the spacial aspects of an external stimulus. Tests which demand recognition of movement in three dimensions are more gravely affected than such a comparatively simple one as localising the position of the stimulated spot; for, with the precautions we habitually adopt, this is an exploration in one dimensional space. Division of the spacial aspects of sensation according to one, two, and three dimensions is obviously arbitrary; but the tests we apply become more or less complex and difficult according as they demand recognition of relations in space of three, two, or one dimensions. Consequently, the records obtained by measuring the extent of passive movement, which can be appreciated in the affected limb, are more gravely and extensively affected than those yielded by our method of testing localisation.

Negative and Positive Manifestations.

(2) The negative manifestations of a lesion appear in terms of the affected level.

Thus, if those parts of the cortex are injured which are associated with speech the consequences are not an affection of some totally different function, such as visual or auditory images, but are shown in terms of defective speech. The business of a clock is to show the time. Faulty action of the mainspring may cause it to go fast, to go slow, or to stop. But we cannot look at the face of the clock and say, "That is strong mainspring time;" all we can say is that the clock is fast. So the negative manifestations of a cortical lesion affecting speech are presented to us in the form of a disturbance of speech, not as a destruction of images.

In the same way, morbid conditions at the reflex level appear as changes in the reflexes; a disturbance of cerebellar activities is seen in incoördinate movement; whilst an injury to the sensory cortex affects the discriminative aspects of sensation—a purely mental function.

(3) A negative lesion produces positive effects by releasing activities normally held under control by the functions of the affected level.

I have already given many illustrations of this law. The phenomena of the mass-reflex after injury to the spinal cord and of spastic rigidity in hemiplegia are examples on the motor side; protopathic sensibility and thalamic over-reaction illustrate similar conditions amongst afferent activities.

Evolution of Functions of Central Nervous System.

(4) The functions of the central nervous system have been slowly evolved by a continuous process of development. The methods by which this gradual progress from lower to higher efficiency has been reached are still manifest in the phenomena of its normal activity.

Thus, the lowest reflexes give the most definite response; there is little or no choice, the answer is inevitable. They are, as Jackson expressed it, highly organised. But further development of the needs of the animal demanded a reaction that was less fixed; some variation must be permitted. This led finally to the domination of many reflex manifestations by consciousness. What at lower levels appeared a variable response became, with the progress of evolution, voluntary control.

Integration of Function.

(5) Integration of function within the nervous system is based on a struggle for expression between many potentially different physiological activities.

Let us consider the following example, drawn from the afferent side. A metal test-tube, containing water at 45° C., normally evokes a sensation of pleasant heat. But it is easy to show that this temperature, suitably applied, stimulates the cold-spots and then appears to be cold. If, by chance, both the end-organs for the reception of heat and cold are absent, pain is produced. Thus, the same temperature is capable of exciting heat, cold, and pain; and yet, under normal circumstances, it evokes a sensation of pleasant warmth. Evidently, the incompatible impulses, due to stimulation of the cold- and pain-spots, are prevented from reaching consciousness.

Such integration occurs at several stages during the passage of afferent impressions through the central nervous system. Those, alike in their qualitative potentialities, are gathered together, whatever may have been their origin, at the periphery. Thus, all impulses capable of arousing pain come together in the spinal cord. In the same way, there are separable paths for those associated with sensations of heat and cold. On higher physiological levels is fought out the struggle for final dominance, and of the warring impulses one group only excites a conscious response.

Processes Concerned in Integration.

The processes by which this integration is rendered possible are three in number. First of all, those impulses potentially of a like sensory quality are gathered together. Secondly, all impulses capable of exciting sensations of a different quality are rejected by the receptors which guard each functional level. The third method is manifested in the phenomena of adaptation. Water at 30° C. may appear under suitable external conditions to be neither hot nor cold. But when the hand has been previously soaked in water at 45° C. for some time a temperature of 30° C. will seem to be cold. Conversely, adaptation to water at 15° C. converts 30° C. into a warm stimulus. This power of adaptation to the conditions of the environment and consequent shifting of the neutral points is one of the most important factors in the mechanics of integration. No stimulus acting over a long period can remain continuously at the same level of efficiency; it leads to a state increasingly favourable to the appearance of the opposite phase of activity. This is the essential condition underlying the tendency to biphasic reaction, so characteristic of the central nervous system.

These three processes—acceptance by similarity, rejection by difference, and biphasic dispositions—form the main features of the physiological functions of the central nervous system. They are factors which lead to integration, whether we are dealing with reflexes or with such psychical acts as sensations.

They are interposed between the vital consequences produced by the impact of a physical stimulus on peripheral end-organs and the final processes of consciousness. We have no right to speak of psycho-physical parallelism; we ought rather to consider, on the one hand, physiologico-physical responses, and, on the other, psycho-physiological relations.

Thus, between the impact of a physical stimulus on the surface of the body and the movement or sensation it evokes, lie the innumerable reactions of the physiological level. Here the form assumed by the conscious response is prepared to a degree scarcely suspected until recently. Many of the impressions produced by a single external stimulus are incompatible with one another, and some of them must give way in the conflict. But the result of the struggle is not fixed or pre-ordained; it may be reversed by some previous

[2] The word "level" is employed throughout in a strictly functional sense. Any one anatomical organ of the central nervous system may exercise functions of more than one physiological level. Thus, the optic thalamus contains not only the termination of the fillet, but also the centre for the affective aspects of sensation. For the same reason a lesion of the post-central cortex not only produces loss of certain sensory faculties, but may also cause hypotonia in the affected parts of the body.

occurrence which has changed the disposition of the central nervous system. The form assumed by a reflex may be determined by the character of the movement which preceded it, and the phenomena of sensory adaptation depend upon the active influence of the past in present events.

Moreover, the general resistance of the central nervous system to certain impulses varies greatly at different times and in different persons. This is particularly evident in the case of pain. We are all subjected to innumerable painful impressions, which under normal conditions never reach consciousness; but if the resistance, either local or general, is lowered these impulses may underlie definite sensations of pain.

We neurologists are brought into daily contact with these diverse functional reactions. We work in the passage-way between the physical universe and the dwelling-place of the mind. We can watch the processes of evolution, visible in the actual behaviour of the central nervous system. We see the coming and the going, and we alone can record which of the many aspirants has conquered the right to enter or to leave that council chamber of human activities.

WAR NEPHRITIS:

A CLINICAL STUDY OF EARLY CASES.

BY H. B. DAY, *M.C.*, M.D. LOND., F.R.C.P. LOND.,
TEMPORARY MAJOR, R.A.M.C.

So many able articles have been written on the subject of war nephritis that some apology seems necessary for an addition to the literature. But in spite of much work on the disease its etiology remains obscure. Several different theories have been put forward and have been discarded, so that at present there is a tendency to dispute the existence of a definite clinical entity and to ascribe the prevalence of renal disease on the Western front to a diversity of agents.

In my work on the medical side at a C.C.S. I observed certain features in the onset and course of war nephritis that seem to throw a fresh light on the nature and origin of this affection. The present paper is based primarily on personal study of 50 cases in the early stages, but I have freely drawn on the richer experience of other writers.

Varieties.

While the great majority of cases of acute nephritis seen at the front correspond to the picture of war nephritis, other forms occur which resemble those seen in civil practice. Most observers agree in dividing cases into three main groups: (1) recurrent nephritis; (2) infective nephritis; (3) war nephritis.

(1) In a certain proportion of patients, with or without a previous history of renal disease, chronic changes are present in the kidneys. Such men may suffer from an exacerbation of their disease under the strain of active service, or may fall easy victims to a superimposed war nephritis. It is notorious that a patient who has apparently made a perfect recovery from war nephritis is liable to a recurrence if sent again to the front. But it is certain that the large majority of patients who contract war nephritis have kidneys which have been quite efficient during arduous training at home.

(2) The term "infective nephritis" has been applied by Keith and Thomson[1] to the acute nephritis which is secondary to an acute focal disease. Such cases are not common in the Army and often show no œdema. They may be distinguished by the concomitant symptoms and by the result of functional tests[1]; they are accordingly excluded from the present series.

(3) War nephritis proper comprises those types of nephritis which seem peculiar to active service conditions. While all grades of severity are encountered, there are two main clinical types: (*a*) the common form characterised by breathlessness, œdema, and the urinary signs of acute nephritis; (*b*) a smaller group distinguished by hæmaturia and involvement of the lower urinary tract as well as of the kidneys, but without œdema as a rule. This group was first classified by Abercrombie under the designation of "lower tract cases."[2]

Owing to the occurrence of mixed types and the occasional transition of the second type into the first no sharp line of distinction can be drawn.

Incidence and Distribution.

A survey of the literature shows substantial agreement on the main features bearing on the origin of the disease:—

Since the American Civil War nephritis has been a rare disease among armies in the field until the present struggle.

War nephritis first appeared on the Western front in the spring of 1915. Since then the rate of incidence has continued about the same.

The disease shows distinct seasonal variations, the rate rising in cold weather and falling during the warm summer months.

Troops in the front line are mainly attacked. Officers are relatively exempt and cases are uncommon among units that are well housed.

Civilians in the war zone have not suffered.

The liability to the disease appears to increase somewhat with age. But this opinion has little statistical evidence to adduce

Previous renal disease or a former attack of war nephritis predisposes to nephritis at the front. In one case of my series there was a family history of nephritis. The father and eldest brother had died of Bright's disease before the war; the second brother and the patient himself (a soldier of 18 years' service) contracted war nephritis; while the two younger brothers had also served in France for a time but had escaped the disease.

Other evidence is negative; it is impossible to regard scarlet fever, mineral poison, or chlorinated water as important factors.

Onset.

The circumstances attending the onset of nephritis are quickly forgotten by a patient. Most cases, however, are sent to a C.C.S. as soon as the diagnosis is made, so that the history taken on admission is fairly reliable.

According to the manner of onset of nephritis patients may be divided into two main groups, (*a*) with antecedent symptoms and (*b*) without.

(*a*) With antecedent symptoms. In about 40 per cent. of cases in this series a period of ill-health or definite illness lasting from 1 to 5 weeks had preceded the symptoms of nephritis. The features of this illness were fairly uniform; the patient felt ill and weak, and complained of headache, with pain in the back and legs. All had carried on for most of the time, though many had been excused duty on account of fever while four patients had been admitted to Field Ambulances for P.U.O.

Respiratory catarrh had accompanied the fever in three patients; others had had a cough for several months (in the winter) but it was not affected by their illness.

Two patients gave a definite history of fever and hæmaturia with pain in the back and frequent micturition that had lasted about three days. This occurred 3½ weeks and 10 days respectively before the appearance of œdema and breathlessness; in the interval both patients had returned to duty.

(*b*) Without antecedent symptoms. In the remaining cases (60 per cent.) signs of kidney disease were among the first to attract attention. Six patients had simply noticed increasing breathlessness with a gradual onset of œdema. In no less than 19 patients the signs of nephritis appeared within a day or two of acute fever. It is true that a record of this fever previous to admission was often unobtainable, but the history and the degree of fever when transferred to the C.C.S. left little doubt but that an even higher temperature had been present before. Soldiers rarely complain of "fever"—a patient with a temperature of 103° will complain of headache, pains elsewhere, faintness, or even constipation! If he shows definite signs of nephritis his temperature is often not taken, since it is unnecessary for diagnosis. When cases of nephritis are not seen until a few days after onset a short initial fever will be missed.

The remaining five patients described a similar acute onset closely following a respiratory catarrh. They showed fever, with coryza or sore-throat and bronchitis.

To sum up, the result of this inquiry was to confirm Abercrombie's statement, founded on 500 cases, that the onset of war nephritis was almost invariably attended or preceded by fever.[2]

Early Symptoms of Nephritis.

The first symptoms of actual nephritis are an increasing breathlessness and the appearance of œdema, generally with more or less cough, headache, and pains in the back and legs. Urinary symptoms are only complained of in the special lower tract type.

For descriptive purposes the features of nephritis may be arranged in three categories: (*a*) respiratory phenomena; (*b*) renal signs; and (*c*) general symptoms.

(*a*) *Respiratory Phenomena.*

The general complaint of dyspnœa in the early stages and the frequency of respiratory complications, especially in winter, are striking features. Breathlessness appears most pronounced in those patients who have continued manual work or marching in the early stages of nephritis. Patients who have been kept at rest on account of fever, &c., before the onset of nephritis rarely exhibit dyspnœa.

The origin of this symptom is uncertain. It is rarely dependent on an acidosis,[1 3] nor does examination show signs of cardiac embarrassment. Changes in the lungs are present, though the dyspnœa seems disproportionate to the physical signs. In all patients with œdema moist crepitations and defective air entry may be found over dependent parts, and often rhonchi scattered over the rest of the lungs. The pathological studies of Dunn and McNee[4] suggest that there may be obstruction of air entry to the infundibula, and it is possible that dyspnœa depends on an œdema of the lungs, rapidly intensified by exertion, such as occurs in cases of phosgene gas poisoning. The symptom is often relieved by coughing, sometimes by change of posture.

(b) *Renal Signs.*

Œdema is often moderate and only apparent on the face and legs. When the patient is put to bed it tends to leave the lower extremities and to accumulate in the lumbar region. Pain in the back is by no means a constant symptom except in cases of hæmaturia, when it is often severe.

Urine.—There is usually a moderate reduction in the volume of urine, marked oliguria is uncommon, and suppression very rare. In some patients the greatest diminution in amount seems to occur some days later than the onset. There is little relation between the daily quantity of urine and the severity of the renal lesion, but a patient with persistent oliguria and marked albuminuria makes a tardy recovery.

Density.—The specific gravity of the urine in the early stages corresponds generally with the amount passed. It never shows a higher concentration than normal, and is often of low density in spite of oliguria.

Albuminuria.—The amount of albumin present varies greatly. In severe cases it may rise to between 1 and 2 per cent.; mild cases may show no more than 1 per 1000 by the time of a remission.

Cellular contents.—Gross hæmaturia is a characteristic of "lower tract" cases, but is common in others without signs of irritation of the urinary passages. Microscopically, red blood corpuscles and leucocytes may always be found in the sediment of early cases. Casts are usually plentiful, epithelial and granular forms predominating.

(c) *General Symptoms.*

These may result from several factors—the causative agent of the nephritis, secondary infections, or the impairment of renal function.

Pyrexia.—In the great majority of cases fever precedes or accompanies the onset, as has been described above. It is usually of short duration, so that the temperature is falling or may have disappeared by the time the patient reaches a C.C.S. The degree, nature, and duration of this initial fever shows little correspondence to any bronchitis or other catarrhal condition present. But a more lasting pyrexia of low grade seen in some patients does appear to depend on a definite semi purulent infection of the bronchial tracts.

The general course of war nephritis is afebrile, the patients frequently showing a subnormal temperature, especially in the morning. Recurrences of pyrexia are not uncommon[3] and will be described later.

The pulse is moderately accelerated during the initial fever, but the rate is soon slowed, even before the temperature has settled. A definite bradycardia is the rule later; in most patients a pulse-rate under 50 may be counted on occasion.

The blood pressure, particularly the systolic reading, generally shows a moderate elevation while the œdema lasts and fever is absent.

Pains.—Pains in the limbs are almost as common as in the back; they appear during the initial fever, but are prolonged into the apyrexial period, and are apt to be aggravated at night, keeping the patient awake. In some patients the pains are located chiefly in the shins, but, as in most cases of trench fever, they are rarely confined to those parts.

Headache is often an early sign and is aggravated by coughing. When persistent it is usually associated with a fairly high blood pressure and urea retention.

Spleen.—The spleen showed enlargement in all my cases, and in 80 per cent. became palpable. When considerable œdema was present examination was unsatisfactory, but on its subsidence the organ could generally be felt. In early cases there is often tenderness on pressure over the splenic area.

Blood.—There are no striking changes in the number and variety of the white cells. A differential count usually shows a reduction of the polynuclears, with a corresponding increase in the mononuclear varieties, particularly the larger forms. In prolonged cases a moderate anæmia develops, but persistent hæmaturia is productive of rapid anæmia proportional to the severity of the symptoms.

Course.

The course of war nephritis is seldom uniform, and it is impossible to judge of the severity and outcome of the disease from the nature of the early symptoms. The first sign of approaching recovery is the spontaneous appearance of a diuresis which quickly reduces the œdema. This critical event may occur within a week of the onset in mild cases or be deferred for a month or longer in other patients, while severe cases may reach a tardy convalescence without sudden polyuria.

I had not studied early cases long in the wards when I was struck by a periodicity that seemed to underlie the manifestations and mark the course of war nephritis. Thus the daily output of urine would increase at regular intervals or show periodical falls with a temporary increase in the albuminuria or a visible return of hæmaturia. A critical diuresis, too, would often be temporarily interrupted for no apparent reason. These slight recurrences or relapses were often accompanied or preceded by a slight variation in body temperature or by a distinct febrile reaction of three days' duration. The pulse varied with such change and the blood pressure fell, though there were no signs of any complicating infection.

At this time I was engaged in studying the splenic enlargement that occurs in trench fever. Major J. H. Lloyd, R.A.M.C., had told me that if percussion were employed as well as palpation a definite increase in the size of the spleen could be made out in trench fever, although it was impossible to feel the organ when it was only moderately enlarged. I had not hitherto employed this method, and was somewhat sceptical of its accuracy. But by dint of constant practice I found one could follow an enlargement of the spleen with surprising ease in most cases, and that the results agreed with the findings on palpation. One could trace an enlargement up to the costal margin where the organ became easily palpable, and note the degree of recession after it could no longer be felt. When percussion alone can be employed it is, of course, necessary to obtain a resonant note over the stomach and colon; in doubtful cases an evening examination was often successful.

The use of this combined method, when daily examinations were made, gave most interesting results in trench fever. In all cases where a previous enlargement was excluded the spleen showed alternate advances and recessions at regular intervals of five or six days (rarely four and a half days). This phenomenon occurred in every form of the disease, whether the fever was relapsing or continuous, and in cases where no definite febrile relapse followed the initial bout a second descent of the spleen was evident at the usual interval.

Various other diseases were taken as controls, but none gave the same phenomenon until I applied this method to cases of war nephritis. In this disease identical changes in the degree of splenic enlargement were constantly found, of the same periodicity as in trench fever. It became at once evident that the signs of periodicity of this disease were closely related to the accompanying changes in the spleen.

The reliability of this method has been tested in diagnosis and prognosis. Thus, it is possible to distinguish a continuous pyrexia due to trench fever from paratyphoid and to foretell an imminent relapse in both trench fever and war nephritis.

Clinical Types.

It will be convenient to consider the course of war nephritis according to the general characters shown. The two main types have been mentioned—the lower tract and the ordinary; this latter, the largest, may be further divided into mild, moderate, and severe.

(1) *Lower tract type.*—There is usually an acute febrile onset, followed by hæmaturia, which is often profuse. The hæmaturia is accompanied by severe pains in the back, often radiating to the groins, and by frequent and painful micturition. Indeed, some patients show virtual incontinence, so great is the irritability of the bladder. There is no dyspnœa or œdema, as a rule, and little reduction in the quantity of urine passed. The colour of the urine may be bright red or brownish—due to some reduction of the blood pigment. Microscopical examination at this stage shows crowds of erythrocytes, many forming casts of the renal tubules. There is hardly more albumin than can be accounted for by the blood present. In my few cases (four in number) obvious hæmaturia lasted 4–5 days, with the exception of one severe case who continued to pass blood for 10 days.

As the hæmaturia declines the urine shows an excess of leucocytes, tract epithelial cells with some cellular and granular casts, and a trace of albumin. Relapses are frequent and are usually accompanied by fever and bone pains. The original case published by Abercrombie[2] had a temperature chart typical of trench fever with its successive relapses. Chart I. is taken from one of my cases, and shows an irregular fever with marked excursions of the spleen; the patient was evacuated before the critical diuresis—seen in similar cases—was reached. Another case showed a large palpable spleen on admission, with but slight subsequent changes in its size. Following the subsidence of the initial fever the urinary excretion fell and continued low for five days; the spleen then receded somewhat and diuresis began. I have seen two cases (not included in this series) with similar relapsing features in which muco-pus took the place of blood; bacteria were absent.

Peters and Stevens[5] have recently published a paper on this type of nephritis, with the results of cystoscopic examination. They found multiple small hæmorrhages into the bladder wall, but no ulceration, and they prove that the bulk of the bleeding comes from the kidney and renal pelvis.

The ultimate prognosis of these cases is good. But, as narrated before, too short a rest may be followed by relapse, with the symptoms of ordinary nephritis.

(2) *Ordinary type with œdema.*—(*a*) *Mild cases.*—Of these there were 8 in the present series of 50. The patients usually gave a distinct history of one or more attacks of fever, in the course of which œdema made its appearance.

Examination of the urine showed albumin and casts on entry, but these signs disappeared when the patients were kept in bed and placed on a milk diet for a day or so. A critical diuresis followed, but in some cases oliguria continued for a time after the œdema and albuminuria had vanished. Charts II. and III. are representative of this group, and show the variations that mark their course better than any verbal description. The after-history of these patients is very favourable; they rarely relapse after evacuation to the base.

(*b*) and (*c*) *Moderate and severe cases.*—From observations at a C.C.S., necessarily limited to the early period of nephritis, it is impossible to make an accurate forecast of the subsequent progress of the patients in these groups. So these two groups will be considered together, so far as their early course is concerned.

Charts IV. and V. are representative of the moderately severe forms of war nephritis; Chart VI. shows a severe case: but they all agree in their fundamental characters, although they have been chosen to illustrate the variations that may occur. Thus Chart IV. shows a case, marked by considerable fever and relapse, in which the urinary excretion is seen to be closely associated with the periodical excursions of the spleen and is barely affected by the pyrexia. Chart V. illustrates another clinical form in which an almost level urinary output runs parallel to a fairly constant degree of splenic enlargement. The first indication of a relapse was on the ninth day of œdema, when the patient complained of pains in the back and legs. Following this, the spleen receded slightly, but there was no appreciable improvement in the condition of the kidneys. However, exactly six days later the spleen enlarged perceptibly and then receded to a greater degree than before, and diuresis at once set in.

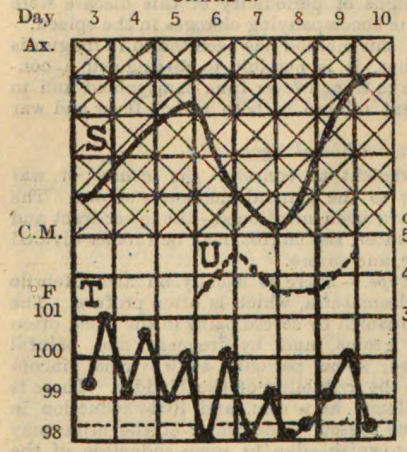
It will be noticed that in the first stage of nephritis a diminution of urinary output is apt to follow after a temporary increase in size of the spleen (Charts II., III., and IV.), but that in the later relapses these phenomena tend to coincide more closely (Charts II. and V.). During the early stage of severe nephritis (Chart VI.) the urine may show only a short temporary increase in amount between the relapses timed by the spleen.

The features of these periodical relapses may be summarised as follows:—General: There is a tendency to febrile

TEMPERATURE CHARTS.

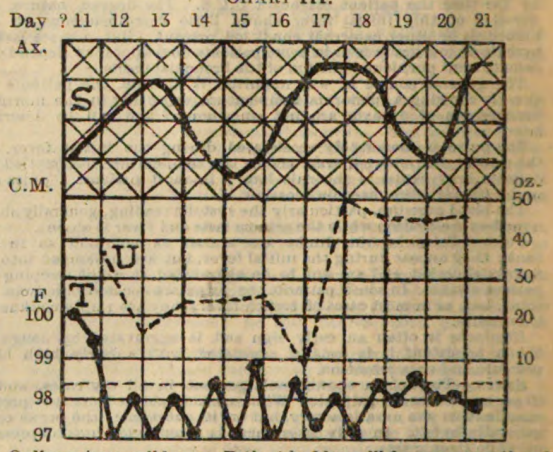
In these temperature charts the daily output of urine is indicated by a broken line (U), reading from the figure column on the right. The upper continuous line shows the variations in size of the spleen (S); an increase is denoted by a descent of this line. The normal size (Ax., mid-axillary line) is taken as the base line above and the costal margin, C.M., below; each space corresponds to a finger-breadth.

CHART I.



Lower tract type. Shows second dip of spleen at the usual time of the first relapse in trench fever (eighth day) quite independent of the pyrexia. Patient was evacuated before any diuresis occurred.

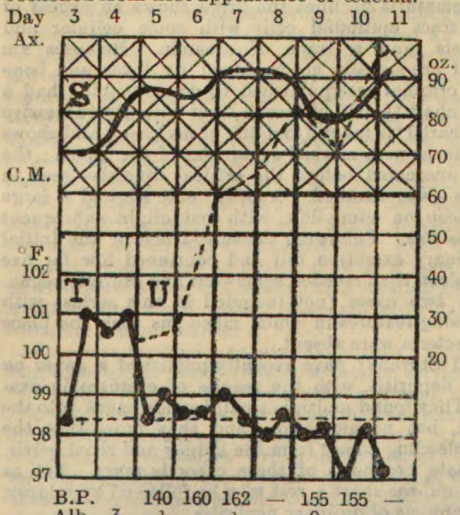
CHART III.



Ordinary type, mild case. Patient had been ill for over a month and had noticed œdema for about 10 days. A trace only of albumin was present and this disappeared with the œdema the day after admission. Note the regular phases of the spleen and continued oliguria after the usual signs of nephritis had disappeared.

CHART II.

In this and following charts day of disease is reckoned from first appearance of œdema.

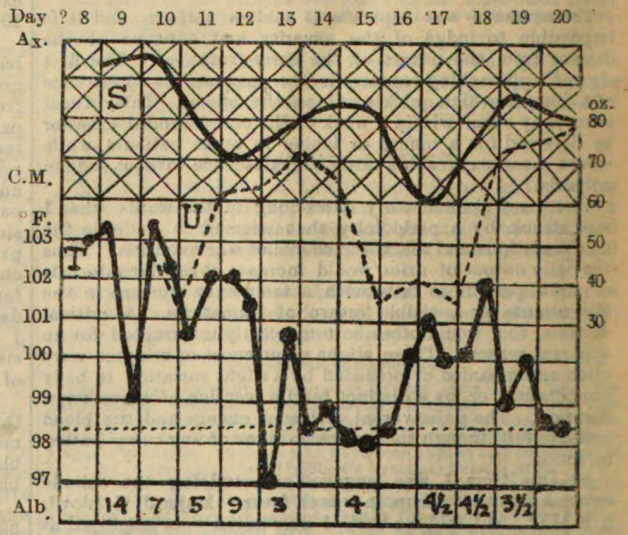


B.P. 140 160 162 — 155 155 —
Alb. 3 ½ — ¼ — 0 — —

B.P., Systolic blood pressure. Alb., Albumin per 1000.

Ordinary type; mild case. Shows early diuresis with disappearance of albumin and œdema. Periodicity indicated by a slight secondary descent of the spleen and interruption of diuresis on ninth day, six days after first recession of the spleen. Note changes in blood pressure.

CHART IV.



Ordinary type, moderately severe. Patient complained of no symptoms except œdema of probably a week's duration. He showed high fever (leucocytes 4800), extreme œdema with much blood and high albumin content in the urine. Lungs clear; no dyspnœa. Chart shows recurrent enlargements of the spleen at 6-days interval and accompanying variations in the urine. The relative independence of the splenic enlargement and the course of the pyrexia is characteristic of the continuous type of trench fever.

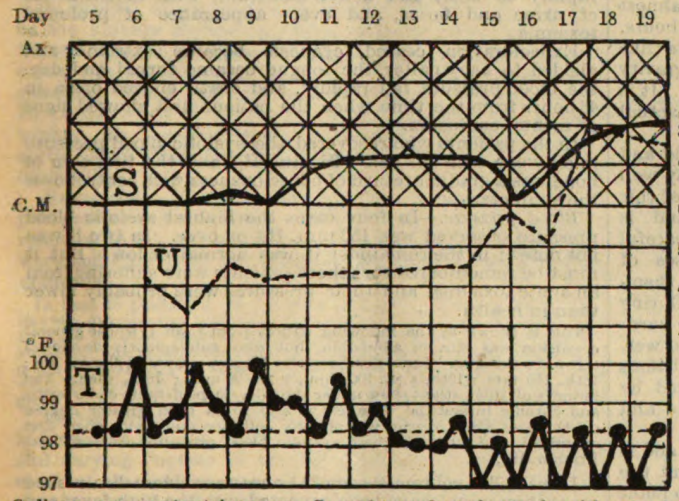
reaction. In slight cases this may only be shown by taking the temperature every two hours; it may be completely absent. The pulse is slightly quickened, and there is usually a definite drop in blood pressure. General aches and pains often precede the relapse by a day.—Spleen: The spleen shows an increase in enlargement and may become tender.—Renal: The excretion of urine falls in amount, while the albuminuria shows a temporary increase, sometimes with a return of hæmaturia. Functional studies reveal a much greater degree of renal block during this phase than is apparent from clinical signs.[1]

So far these periodical recurrences have been described as simply interrupting the course of the disease. But any one of them may reach serious proportions, so that the kidney may suffer more severely in a relapse than in the original attack.

Diuresis: A critical diuresis may occur early and be uninterrupted; in one of my cases as much as 174 oz. were excreted in the 24 hours, although the patient was kept on the same amount of fluid as before. More commonly the diuresis is temporarily checked by one of the periodical phases that characterise the disease. During this diuresis the blood pressure remains elevated and the urinary concentration falls. The œdema rapidly diminishes and the kidneys excrete retained products. Following the polyuria the blood pressure falls and the specific gravity of the urine slowly rises, the albumin and casts disappear or are reduced to a low amount. How long the spleen may continue to exhibit enlargement I am unable to say.

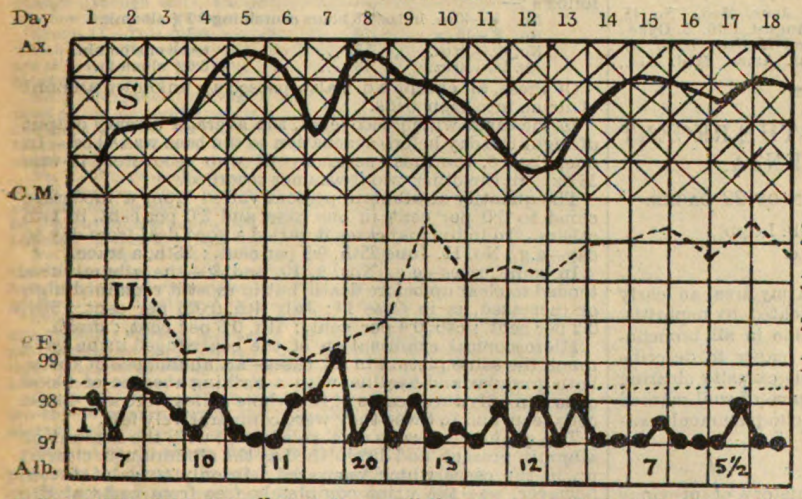
The further course of nephritis as seen at the base is well described by Keith and Thomson.[1] They divide cases into resolving and non-resolving groups; in each relapses are frequent and slight recurrences numerous. Resolving cases exhibit a distinct diuresis, with a rapid disappearance of œdema, diminution in the albuminuria, and a relatively good renal function. The non-resolving group is characterised by the slow disappearance of œdema and delayed diuresis, persistence of blood and albumin in the urine, the development of permanent retinal changes, and grave impairment of renal function.

CHART V.



Ordinary case, moderately severe. Gave history of nasal catarrh, with pains in the legs and fever one week before admission. Dyspnœa, cough, and œdema appeared about three days after onset of his illness. He had a general bronchitis which continued throughout. Chart shows a closely parallel course between the excretion of urine and the degree of enlargement of the spleen. Note check of terminal diuresis; it would probably proceed after next phase of spleen.

CHART VI.



Ordinary type, severe case. No symptoms until the appearance of œdema the day of admission. Shows an almost apyrexial course, with unusually well-marked excursions of the spleen. The periodicity governing the urinary features can be appreciated only by observing the time-marking of the spleen. The first relapse was more severe than the second and the kidneys were severely damaged; signs of mild uræmia were present (blood urea 0·145). Note slight indications of the relapses in the temperature readings.

Complications.

Respiratory.—Bronchitis is very common in the early stages, particularly in patients with considerable œdema, or who are suffering from a winter cough—so common in the trenches. As a rule it disappears with the subsidence of œdema, but may develop into a septic process with purulent sputum and slight fever. Two of my patients developed lobar pneumonia; two others fell victims to the recent epidemic of "influenza" when the wards were full of such cases. But it was remarkable that these complications had very little effect on the course of the nephritis.

It has been suggested that the relapses seen in war nephritis are due to complications in most cases. My experience does not support this view, and it is possible that the converse is true. For patients with febrile recurrences show an aggravation of an existing bronchitis with a return of their fever, and may develop pneumonia as an extension.

Uræmia.—Other complications, such as uræmia, retinitis, cerebral hæmorrhages, &c., may occur, as in other forms of nephritis. These have been fully described by observers of larger experience than the present writer, and only need to be mentioned.[1 2 3]

Summary and Discussion.

The course of war nephritis is marked by more or less evident changes at regular intervals of five or six days. The only other disease prevalent in the war that exhibits a similar periodicity is trench fever. Hence the question arises, Is war nephritis a complication of trench fever?

As far as the distribution and general features of war nephritis are concerned, there appears no valid objection to this suggested relationship. It is generally admitted that certain cases of war nephritis show all the signs of trench fever; but the occurrence of such cases is not too frequent to be explained by mere coincidence. For this reason I have refrained from choosing such examples for the illustrative charts. On the other hand, no one who has had a large experience of trench fever in the line will deny the great prevalence of mild types, characterised either by a single bout of fever of moderate range or by a very low grade of pyrexia throughout. The liability of trench fever to recur months after apparent recovery is notorious. After exhaustion or chill, exposure to poison gas, or receiving a wound, a patient may suddenly develop acute fever again. This may happen to patients who

have no recollection of previous fever, in the same way apparently that a person leaving the tropics may show his first attack of malaria on reaching a cold climate. In these cases, it may be remarked, a chronic enlargement of the spleen is usually present.

These facts show that the types of fever encountered in war nephritis and its modes of onset may be paralleled in trench fever. But when we consider the identity of the diseases from a closer aspect we are confronted by points of difference: (*a*) Ordinary and experimental cases of trench fever, as studied in the wards, show little or no tendency to develop nephritis. (*b*) There is no proportion between the severity of the fever in war nephritis and the degree of renal damage. Many severe cases of nephritis show no definite fever. (*c*) War nephritis has a seasonal variation which is not apparent in trench fever.

Before dealing with these points it is worth while inquiring, What signs of renal damage are shown by ordinary cases of trench fever? It is well known that albumin, often accompanied by microscopical amounts of blood, is often present in the urine during the initial stage of trench fever. But this is not the most striking sign of renal damage. If the urinary excretion be watched certain patients will show a remarkable oliguria independent of the pyrexia and possible early albuminuria. The urinary flow may be almost suppressed for a period varying from 12 to 24 hours. Others may show a marked reduction for several days (like Chart III.) or pass a moderate quantity of low specific gravity urine without albumin after the fever has subsided. It is highly probable that this renal injury may progress to actual nephritis under unfavourable circumstances.

The seasonal incidence of war nephritis points to cold and exposure as predisposing agents. These factors may well turn the scale in trench fever. In an acute attack of this malady the patient is disabled by high fever, and is accordingly removed to shelter and receives careful attention. But a large proportion of milder cases of trench fever do not report sick or may simply avail themselves of a day's rest when circumstances permit. During his illness, therefore, the patient experiences all the hardships of life at the front. He is exposed to cold and wet, especially in the winter, and has a full meat diet, conditions which throw a considerable strain on kidneys injured by trench fever infection. Resolution may be impossible and nephritis results.

This theory meets the main objections put forward and is founded on clinical facts. But it is somewhat beyond the scope of this paper to follow further. My object is to point out a definite periodicity that distinguishes war nephritis proper, and to call attention to the close similarity between its general features and those of trench fever. Whether or not this coincidence depends on an identical infection can only be satisfactorily settled by experimental and laboratory work.

NEPHRITIS IN RELATION TO THE RECENT EPIDEMIC OF INFLUENZA.

THE RESULTS OF AN INVESTIGATION OF 22 CASES.

BY C. P. SYMONDS, M.R.C.P. LOND.,
TEMPORARY CAPTAIN, R.A.M.C.

DURING the recent epidemic in the Army area an early fatal case of broncho-pneumonia, complicated by nephritis, led to a careful investigation of the urine in all broncho-pneumonias. It is the purpose of this paper to describe briefly a series of 22 cases admitted to this casualty clearing station with influenza, in which the presence of well-marked signs of renal disease in addition to broncho-pneumonia was associated with a high rate of mortality.

Symptomatology.

Previous illness.—No patient gave a history of previous nephritis or of scarlet fever. Four stated that they had never had any illness. Eleven had suffered from illnesses as follows: Nos. 4 and 11 influenza; Nos. 12 and 14 pneumonia; No. 1 "fits since he can remember"; No. 7 syphilis; No. 9 asthma and bronchitis; No. 13 measles and pleurisy; No. 16 malaria and dysentery in Palestine; No. 17 gassed a month previously; No. 19 colitis in India. From the remaining seven no histories were obtained.

Age.—The age in 18 cases ranged from 19 to 37, the average being 25·3 years. The age was not discovered in the remaining four cases.

Physique.—The average physique in the series was good, only two of the patients being in a category lower than "A," No. 9 for asthma and No. 20 for defective vision.

History of onset.—This was similar to that of other cases of broncho-pneumonia following influenza—a secondary rise of temperature, with breathlessness, pains behind the sternum or in the sides, and cough with purulent expectoration.

Clinical observations.—In only one case of the series (No. 1) was marked œdema observed, the distribution of the fluid in this case being general and the amount extreme. One case (No. 22) gave a history of swelling of the face and feet a day before admission, and was distinctly puffy under the eyes when first seen. In nine of the others it was noted that their faces "looked swollen," but there was no palpable œdema. The remainder showed no signs of fluid retention.

The physical signs in the chest were similar to those observed in other broncho-pneumonias, and varied only in degree and distribution, but dyspnœa seemed more urgent in relation to the amount of lung involved than in cases uncomplicated by nephritis.

The most constant feature of the nephritic cases was the early onset of an acute confusional mental state, progressing rapidly to noisy and active delirium, with incontinence of urine and fæces, and every appearance of profound toxæmia.

Expectoration ceased, cyanosis became extreme and yielded to ashy pallor, the tongue became furred and dry, the blood pressure fell rapidly, and death ensued often in 48 hours from the time when the patient first showed signs of mental confusion.

In the patients who recovered the systolic blood pressure in only one case fell below 95 mm. Hg, and the first sign of hope was a gradual return of consciousness with control over the sphincters.

Blood pressure.—In four cases the highest systolic blood pressure observed was 150 mm. Hg or over. In two it was not noted; in the remainder it was normal or low. But it must be remembered that these patients were suffering from an acute toxæmia, and their pressures were probably lower than in health.

This is shown by the following figures from Case 1, whose general condition was fair on admission, but who subsequently developed signs of poisoning. June 12th, systolic blood pressure, 170 mm. Hg; 13th, 140 mm.; 15th, A.M., 100 mm., P.M., 90 mm.; 16th, died. The kidneys of this patient show under the microscope definite endarteritis and chronic interstitial changes, as also to an even greater degree do those of Case 5, who was already delirious and livid when first examined, and whose highest systolic blood pressure observed was 105 mm. Hg.

Urine.—The volume in each 24 hours was seldom diminished more than might have been expected with the high fever and pneumonia, the lowest average daily output for the first two days being 30 oz. per 24 hours in Case 20, the highest, 65 oz., in Cases 6 and 10.

In the later stages it was, as a rule, impossible to get an accurate measurement owing to incontinence, but in four fatal cases the quantities collected in the last hours were as follows:—

No. 4.—40 oz.	in last	18	hours	containing 0·1% albumin.
No. 6.—15 oz.	,,	20	,,	,, 0·3% ,,
No. 10.—15 oz.	,,	18	,,	,, trace of albumin.
No. 14.—30 oz.	,,	18	,,	,, 0·6% albumin.

Of these, all except No. 4 also passed an unknown amount of urine into their beds.

In the cases which recovered, the average urinary output of eight the day before evacuation to the base was 49 oz. In one, Case 8, the most seriously ill who recovered, it was 35 oz. In the other two it was not recorded.

The quantity of albumin present varied from a moderate cloud to 3·0 per cent. in one case, and 2·0 per cent. in two others. In individual cases it varied a good deal from day to day—e.g., No. 11, June 25th, 0·5 per cent.; 26th, a trace.

In some cases—e.g., Nos. 5, 10, and 20—the albuminuria tended to clear up before death, but in most it remained high or increased, as in Case 14: July 4th, 0·025 per cent.; 5th, 0·2 per cent.; 6th, 0·4 per cent.; 7th, 0·6 per cent.; death.

Microscopical examination of the centrifuged urine gave much the same picture in all cases—an abundance of casts, both granular and hyaline, with a striking absence of blood cells; in only three cases of the whole series were any blood cells seen, and in these they were comparatively few.

The quantity of casts as a rule varied with the amount of albumin present, and diminished as the albuminuria cleared up in the cases which recovered. In only three of these, however, was the urine completely free from casts at the time they were evacuated to the base, although their temperatures had been normal for some days.

The casts also diminished in quantity with the decrease of albumin before death in Cases 5, 10, and 20, and it has been suggested that death in these cases was due to secondary infection of the lungs by organisms whose toxins had not

that selective hostility for the kidneys which those of the primary infective agent would appear to have.

Eye changes.—Captain H. V. White, R.A.M.C., kindly examined the fundi for me in 19 of the 22 cases. In no case were hæmorrhages or retinitis observed, but in Cases 1 and 4 œdema of the discs was noted before death.

Treatment.

Treatment was directed mainly towards the broncho-pneumonia, the patients being encouraged by every means to expectorate the purulent fluid which filled their bronchi. In the cases with high blood pressure venesection was performed with temporary relief of the cyanosis and dyspnœa. Oxygen was given freely by Haldane's apparatus or through intranasal catheters. For the nephritis the motions were kept loose and in some cases hot-air baths were given.

Sodium bicarbonate was given into the veins of two cases without apparent effect; in another patient draughts *ad libitum* of a 5 per cent. solution were followed by a return to sanity after a long period of delirium, and he eventually recovered; but another progressed from bad to worse under the same treatment.

Results of Post-mortem Examinations.

Morbid anatomy.—The lungs showed the appearances of purulent bronchitis and confluent broncho-pneumonia which were typical of all fatal cases seen in this epidemic. None of the kidneys showed any gross changes to the naked eye beyond a slightly adherent capsule. The spleen in most cases was enlarged and firm. In Case 1 the tissues were generally sodden, with excess of fluid in the serous cavities. In Cases 13 and 14 there were signs of terminal acute peritonitis. In Case 7 there was a syphilitic vegetation on the aortic valves (corresponding to a musical systolic bruit heard during life).

Bacteriology.—Routine bacteriological examination was not practicable, and the term influenza is used provisionally in referring to this series of cases; it may be assumed that they were suffering from infection by the causal organism of the epidemic.

In Case 20 Captain J. W. McLeod, R.A.M.C., performed the post-mortem examination and has kindly allowed me to refer to his notes. In films he found small Gram-negative bacilli in pus from the trachea and from the bronchioles; and in culture from the cut surface of a patch of solid lung he obtained a growth of a Gram-negative bacillus with the morphology of *B. Pfeiffer*, but a subculture of this failed to grow.

Morbid histology *.—Microscopical examination of the kidneys was made in the 11 fatal cases; all show congestion and varying degrees of tubular degeneration, but as post-mortem examination was in some cases delayed and the weather was hot, detailed examination of the tubules is of not much value. With regard to other abnormalities, however, the sections may be grouped as follows:—

Group I.—These sections from Cases 1, 3, 5, and 20 all show more or less evidence of an early stage of chronic interstitial nephritis—i.e., thickening of capsule, increase of interstitial connective tissue, end-arteritis, and thickening of Bowman's capsules in the glomeruli. These changes, though early, are definite and widespread—not localised to any one area of a particular section.

Group II.—This group comprises the kidneys of Cases 4, 6, and 13, in which careful search reveals appearances which, though not uniform, are suggestive of pre-existing renal damage. The notes upon these are briefly given below.

No. 4.—No general increase in connective tissue; no endarteritis. In most of the glomeruli there is a fibrinous-looking coagulum filling up the space between the vascular tuft and Bowman's capsule. Hyaline thickening of some of the glomerular capsules, and one completely obliterated. Duration of fatal illness, eight days.

No. 6.—No general increase in connective tissue; no endarteritis. Some glomeruli show proliferation of endothelial lining and hyaline swelling of Bowman's capsules; in the boundary area there is increase in the perivascular connective tissue. Many hyaline casts in convoluted tubules. Duration of fatal illness, 12 days.

No. 13.—Capsule not thickened; patchy increase of hyaline connective tissue round arterioles and in Bowman's capsules. No endarteritis, but the glomerular arterioles look thicker than normal; a single fibroid glomerulus. Duration of fatal illness, eight days.

Group III., Case 7.—This section shows considerable thickening of the capsule; marked increase of connective tissue, both intertubular and periglomerular; this is of fibro-hyaline consistency and poor in nuclei, appearing young and œdematous. The glomeruli are not contracted; no endarteritis. Duration of fatal illness, five days.

Group IV.—In Cases 2, 10, and 14 the sections show no abnormalities worthy of remark except the congestion and tubular degeneration already described as being common to all.

Summing up these findings, it may be said that the four patients of Group I. were all, though apparently healthy, suffering from an insidious form of renal disease before they took the influenza. The significance of the changes described in Group II. cannot be estimated at its true value without comparison with the histological appearances of the kidneys of "normal" men within the same age limits. They suggest a very early stage of the process responsible for the lesions in Group I. The impression gained in Case 7 is that the interstitial changes are of longer standing than the five days' duration of the terminal illness.

Sections of the spleen were examined in nine cases.

In Case 14 only were definite hæmorrhages found corresponding to those described by Tytler and Ryle and others as typical of trench nephritis. In this case the hæmorrhages show up well in a spleen which is not unduly congested and are in process of invasion by large mononuclear cells which have taken up pigment.

In several others there is an extreme degree of congestion producing in one or two instances diffuse patches of agglomerated red cells not unlike the appearances shown in Tytler and Ryle's microphotograph No. 20 in their paper; but in the absence of any evidence of organisation and on comparison with specimens showing lesser degrees of congestion, I have hesitated to pronounce them hæmorrhages.

Sections of the lung show consolidation of broncho-pneumonic type.

The sections in all cases were prepared by Captain Adrian Stokes, R.A.M.C., for whose help and advice I am most grateful.

Following in tabular form are some of the main points in the cases.

No.	Urine.	Albumin-uria.(1)	Casts.(1)	Blood cells.	B.P.	Result.	Albumin-uria.(2)	Casts.(2)
1	48 oz.	+++*	++	A few.	170	D.	+++*	++
2	—	++*	++	,,	—	D.	++*	++
3	—	++*	++	,,	160	D.	++*	++
4	34 oz.	0·1%	++	None.	150	D.	0·1%	++

Urine: Daily output; average for first two days of observation. Albuminuria (1) = Highest degree noted; (2) when last observed. Casts (1) = Quantity at height of illness; (2) when last observed. B.P. = Highest systolic blood pressure noted (mm. Hg).

Summary and Conclusions.

1. These cases on the whole did not present a clinical picture typical of nephritis, and in most instances this would not have been suspected without examination of the urine. It was rather the man who looked poisoned by his broncho-pneumonia whose urine was found to be loaded with albumin and casts; delirium and collapse were the outstanding symptoms of the patient whose nervous centres and renal epithelium alike were overwhelmed by the toxins absorbed from his pus-sodden lungs. It is easy to imagine that once the kidney was damaged with consequently impaired ability to excrete the poisonous substances, the prognosis would be proportionately worse, and this vicious circle will account for the 50 per cent. mortality in the series of cases recorded, and the fact that, of a total of 21 men who died of influenzal broncho-pneumonia 11, as described above, had signs of severe renal damage.

On the laboratory side the abundance of casts with comparative absence of blood cells supports the view that the process in the kidney was one of acute degeneration rather than acute inflammation.

2. Microscopical examination of the kidneys shows in at least four cases (possibly also four others) evidence of pre-existing renal disease. This is out of a total of 21 deaths in all from broncho-pneumonia during the period under review, an incidence of at least 19 per cent. of "latent nephritics." The incidence of latent nephritis among "healthy" troops has been estimated from examinations of the urine by Maclean[2] working at the base at not more than 2 per cent.,

* This section was illustrated by a number of micro-photographs, the reproduction of which has not yet been executed.

by McLeod[3] among troops in the forward area at a rather higher figure. The present observations indicate either that the real proportion of men with latent nephritis among healthy front-line troops is much higher than it has been judged from examination of urines or that persons whose kidneys are previously damaged by disease are especially prone to die from broncho-pneumonia in this epidemic—the latter explanation appearing the more probable.

I have pleasure in thanking Lieutenant-Colonel J. Graham Martin, R.A.M.C. (T.F.), for permission to publish this paper, and the officers at his casualty clearing station for helping me to collect the material for it.

TUBERCULOUS DISEASE OF HIP-JOINT.

A SIGN OF PATHOLOGICAL ACTIVITY.

BY H. J. GAUVAIN, M.A., M.D., M.CH. CANTAB.,
MEDICAL SUPERINTENDENT, LORD MAYOR TRELOAR CRIPPLES' HOSPITAL AND COLLEGE, ALTON, HANTS.

THE desirability of a trustworthy clinical indication of activity of tuberculous disease of the hip-joint which has long required treatment is, I trust, sufficient justification for the record of a sign the value of which has been confirmed by a somewhat lengthy experience in the treatment of surgical tuberculosis.

The Insufficiency of the Usual Indications.

The majority of text books are curiously vague, and rarely helpful in assisting those responsible for the treatment of tuberculous disease of the hip-joint in arriving at a decision as to when hip disease may be reasonably regarded as inactive. That there exists much doubt on this point I am convinced by the frequency with which an opinion is sought, and any additional aid in arriving at a conclusion may therefore be welcomed.

The time during which activity persists necessarily varies within wide limits, depending on the virulence of the infection, the resistance of the patient, the nature and extent of the lesion, the treatment adopted, the conditions under which treatment is applied, the existence of complications, &c. Obviously, merely to state a period during which recumbency, immobilisation and extension, or any other form of treatment for active disease of the hip-joint should be enforced is unscientific and of little value, for it does not take into account the varying factors already enumerated.

The temperature chart is of no value because, under suitable conditions, the temperature of an uncomplicated case of hip disease speedily becomes normal, and should remain so even while the disease is active. Pain likewise affords no clue, as with adequate treatment all pain is rapidly relieved and, indeed, is absent long before the disease becomes quiescent. The presence or absence of deformity, abscess, sinus, or added infection affords no sufficient guide, though each may, and should, influence decision.

In the absence of bony ankylosis, however, there remains one factor which is of supreme importance. In tuberculous disease of the hip-joint the most constant and most marked evidence of activity is spasm of the muscles about the affected joint. As the disease becomes less acute spasm becomes increasingly difficult to demonstrate, until eventually it completely disappears. It may last be elicited in the following manner.

Description of the Sign.

If the femur, on the affected side, be grasped firmly in the region of the condyles it will be found that the head of the bone may be gently rotated within the acetabulum, either inward or outward, through a varying but often considerable angle. When this movement is checked, but the disease remains active, a further slight sharp rotation is instantly followed by spasmodic muscular contraction, not confined to muscles about the joint but extending to the abdomen and visible in the abdominal muscles, or still more easily demonstrated if the palm of the hand is placed on the abdomen between the iliac spines. Quite a gentle and painless but sharp rotary movement is sufficient to provoke this reflex spasm of the abdominal muscles. Naturally, it would not be attempted where the disease is obviously active, but in just those cases where doubt exists I have found it a sign of the utmost value. With a little practice the sign is easily and safely obtained if the disease is active.

Confirmatory evidence of activity, as indicated by muscular spasm, may at the same time be demonstrated in the following manner. In a child a finger and thumb of the hand not engaged in grasping the femoral condyles may be applied simultaneously to the two anterior superior iliac spines. During the first rotation of the femur on the affected side no movement is conveyed to the iliac spines. When, however, rotation has been checked and is sharply but gently continued, exaggerated movement in the same direction is transmitted to the iliac spines. With a healthy joint this type of movement is not apparent, with a hip-joint affected with improving but still active tuberculous disease it is very striking, even when the disease otherwise appears to be quiescent.

Bearing of the Sign on Treatment.

The significance of this induced spasm calls for brief comment. Failure to elicit it may not necessarily imply that there is no active disease, though very probably the disease is quiescent. Its presence certainly indicates an active lesion.

Its bearing on treatment depends upon the view those responsible for the patient take as to the nature of the treatment which should be adopted. Briefly stated, I hold the view that acute tuberculous disease of the hip-joint should be treated with the patient recumbent, the lesion immobilised, and extension applied to the limb of the affected joint to prevent or correct deformity and aid in the abolition of muscular spasm. It may be granted that there are occasions when this line of treatment should be modified, or, indeed, not employed; but, speaking generally, it will be found most effective, and should be continued at least as long as the induced spasm described above is demonstrable.

The value of the sign lies in the fact that without such a definite indication of activity ambulatory treatment may be too early permitted, with grave risk of relapse, further extension of the disease, greater disorganisation of the joint, and production of deformity. On the other hand, without means of demonstrating that spasm has ceased recumbency may be unduly or needlessly prolonged, to the detriment of the patient's health and happiness.

Emphasis should be laid on the fact that while failure to elicit the sign is a certain indication that there is no longer muscular spasm about the affected joint, that alone does not justify the assumption that the disease is finally arrested. Prolonged care in treatment is still called for. Efficient immobilisation should still be enforced and the joint protected from strain or injury, but with these precautions observed ambulatory treatment may, as a general rule, be with confidence permitted and extension on the affected joint discontinued.

Prognosis: Significance in Early Cases.

It may be added that if recumbency, immobilisation, and extension be enforced until the sign of activity described cannot be demonstrated, not only may a very favourable prognosis be in general given, but also a very useful range of movement in the attacked joint may be anticipated. Such prognosis naturally presupposes that the joint is effectively immobilised and guarded when ambulatory treatment is first permitted and the patient is given the benefit of that adequate after-care and skilled observation which so serious a condition as tuberculous disease of the hip-joint demands.

The sign also has diagnostic significance in early cases of tuberculous disease of the hip-joint, but it has not the peculiar value in these that may be attached to it later on. In cases of tuberculous disease of the hip-joint which are becoming quiescent it may be considered almost to stand alone as marking, with peculiar exactness, the point where spasm of the muscles and corresponding activity of the disease ceases, and its unique character on that account renders it of especial value.

In early hip disease it is but one of many signs of the onset of tubercle, but it affords confirmatory evidence of active inflammation about the hip-joint which possesses a value not to be despised, and which, in conjunction with other signs of tuberculous disease of the hip-joint, contributes additional evidence of importance in early diagnosis.

A ROUTINE TREATMENT FOR
SEPTIC SORES AND NILE BOILS.

By H. WARREN CROWE, M.D. Oxon.,
TEMPORARY CAPTAIN, R.A.M.C.

SEPTIC sores and Nile boils have been from time to time extremely common among the forces in Egypt. It appears that similar troubles affect the Salonika and Mesopotamia armies. When the lesions are severe either condition is incapacitating and may involve the withdrawal of many men from the fighting line. The routine of treatment which I now venture to advocate is certainly capable of being used in the field. If the same results can be obtained at the front as in a base hospital evacuations of sick due to these diseases should be almost eliminated.

I.—*Septic Sores.*

The name septic sores is now hallowed by use, and I adopt it in preference to tropical ulcer, veldt sore, barcoo rot, and I.C.T. (an army title signifying inflammation of connective tissue). I.C.T. is too comprehensive a name, veldt sore and barcoo rot are local titles, whilst tropical ulcer should, I think, only connote that condition associated with the Leishman-Donovan body. Of this I have had no experience. It is undoubtedly rare amongst the troops in Egypt and Palestine.

The most recent work done on the subject appeared in a paper entitled "Observations on the Pathology of Barcoo Rot (Veldt Sore?)."[1] Lieutenant-Colonel C. J. Martin, F.R.S., A.A.M.C., discusses the question in the light of his experience in the Sinai Peninsula during the summer of 1916. He gives an excellent résumé of the study of veldt sores, which he takes to be an identical condition. Colonel Martin considers the immediate cause to be an infection of the hair follicles with staphylococci of low virulence. He does not, however, exclude the possibility of some environmental factor which may dispose to the disease. He quotes Bishop Harman's conviction that "the restricted range in diet during operations on the veldt is an essential factor in bringing about the condition."

Colonel Martin's description of the sores is so clear that I venture to give it in full:—

> The patient may remember abrading the skin, but whether or not, the first sign is usually a bleb or blister containing thin, watery pus and surrounded by an area of slightly inflamed skin. The blister may be the size of a sixpence or even larger, but before it reaches this size it is usually broken. The denuded surface shows little tendency to heal, but slowly extends at its margins, at the same time deepening until there are no more epithelial structures left. The ulcer, however, remains shallow, and it is unusual for the fibrous layer of the skin to be destroyed unless it becomes infected with virulent staphylococci. The glands are not inflamed unless secondary infection occurs, and there are no constitutional symptoms.
>
> When healing has occurred areas of glossy skin more or less denuded of hairs and sweat glands are left. Cicatrisation does not occur unless the true skin is destroyed. Infection of fresh areas of skin in the neighbourhood is usual, so that the patient has several ulcers of different ages. The disease in its minor forms is extremely annoying, and, when the ulcers have become large, incapacitating.

Colonel Martin also makes this statement: "The pus from the early blisters before they were broken afforded only growths of staphylococci." Bishop Harman also found only staphylococci.

Other valuable, though I believe unpublished, work has been done by Captain Craig, R.A.M.C., on septic sores in the Sinai Peninsula, also in 1916. He found true diphtheria bacilli in some 25 per cent. of sores, and noticed diphtheritic sequelæ to follow in a certain number of cases. I should add that Colonel Martin also mentioned having isolated true diphtheria bacilli in one instance.

During the period covered by my own observations (at the base, at any rate) diphtheria bacilli were rare. I found diphtheria-like organisms in about 5 per cent. of all sores examined. The sores in which these occurred were distinguished from the usual ulcers by their depth and by a tough, blackened, dry membrane which covered them, and which I only succeeded in dislodging with the help of a digestive ferment. The membrane contained diphtheria-like organisms in large numbers. I regarded the condition as due to a secondary diphtheritic infection imposed on a primary streptococcal lesion, since, after removal of the membrane and cleaning up with alcohol, in more than half these membranous sores streptococci were isolated in pure culture (the remainder being sterile). At the time there was quite a considerable epidemic of mild diphtheria in progress.

Altogether I cultured 103 cases of septic sores. From the outset also I treated the patients with vaccines, either autogenous or stock, prepared from similar conditions. The indications derived from this treatment were of great assistance to me. For example, I noticed that although staphylococci could be cultured from almost any open sore, yet vaccines of this organism produced no apparent effect.

From the first unopened blister which I punctured a streptococcus grew in pure culture; it was delicate, and seemed to require serum or blood for its successful cultivation. From the pus of open sores streptococci could only occasionally be isolated owing to overgrowth by other organisms. I therefore adopted the technique of cleaning up a sore with absolute alcohol and planting out on Löffler's or other blood medium the serum which presently would ooze up from the bottom. This serum was sterile in about 30 per cent. of the sores examined, but as cases were taken successively and without selection a number of small healing sores were included, and these were the source of most of the negative cultures. Where fresh active sores were thus treated a negative was rare.

Of 98 non-membranous sores in 98 different people cultured by the technique just described 65 were positive and 33 were negative. The table shows the percentages of the different organisms in these positive cultures.

		Per cent.
Streptococci occurred in	59 =	90·8
,, in pure culture in	39 =	60·0
,, with staphylococci in ...	17 =	26·1
,, with diphtheroids in ...	3 =	4·6
Staphylococci in pure culture in	4 =	6·2
Diphtheroids alone in	0 =	0

A further point which became very clear during the work was that the more thoroughly an ulcer was cleaned up with alcohol the more certainly were streptococci found in pure culture. A certain number of sores which yielded a mixed growth of strepto- and staphylococci at the first culture showed streptococci only later on. These are classed as "streptococci with staphylococci" in the table.

Summarising the various findings, my own and those of others described above, the reader will notice that staphylococci alone are found by several observers, including Colonel Martin; diphtheria bacilli in a large proportion by another; and finally, in my own series, there can hardly be any doubt that streptococci were the active agent. If any further evidence is required to confirm this, I may add that inoculations of small doses of streptococcal vaccine, either autogenous or polyvalent stock (made from septic sores), produced a very marked focal reaction with an outpouring of serum, and that larger doses were followed by an outbreak of fresh blisters.

It seems probable from a consideration of all the evidence that we are dealing with a condition directly due to some cause associated with a hot dry climate or with a special dietary, and that in every case the lesion thus produced is infected with the prevailing microbes. It does not seem that there is sufficient evidence to point to any particular climatic agent or form of diet as the actual cause of septic sores.

II.—*Nile Boils.*

These are a totally different lesion from septic sores, though in certain stages somewhat resembling them. They are also quite plainly different from the usual boil seen in temperate climates. I have not been able to discover a publication describing the pathology, nor, unfortunately, have I had the opportunity of investigating the histology myself. But the naked-eye appearances alone are sufficiently unusual to warrant a distinctive title. The earliest appearance of the Nile boil is a tiny, almost pin-head, blister, and at this stage it is not unlike an early minute septic sore. Very soon, however, this small head becomes surrounded with a bright red areola about the size of a sixpence. Some virulent boils start with a larger areola, even up to the size of a five-shilling piece, and the whitish, blister-like head is of a corresponding size. If at this early stage, which is within 24 hours of the commencement, the head be lifted off, within will be seen a small slough about the size of an ordinary pin's head. After 48 hours the appearance is, as a rule, still the same, only larger. During this first period the boil is intensely tender to the touch, as, in fact, it is during its whole course. The second stage now begins by a general hardening and swelling of the surrounding tissues, which

[1] Brit. Med. Jour., June 9th, 1917, p. 761.

become a dusky purple. Gradually a hard, brawny lump forms, which may be any size, from a hazel nut to the half of a large orange. The central slough also steadily grows in size, and squeezing or opening with a knife only results in the expulsion of a little clear serum. At some point in this slow evolution, which may take three weeks or longer, the boil begins to break down, pus is formed, the slough or core is gradually extruded, and eventually a deep-seated ulcer is left, which slowly heals by granulating from the bottom. In the later stages the larger boils resemble an ordinary carbuncle. There is considerable destruction of tissue and a deeply pitted, purplish scar always results. Note here the difference from septic sores in which scarring is usually absent. The distinctive features, then, of the Nile boil are the initial slough, with its red areola, the extreme tenderness, and the complete absence of pus until the last stage.

Chalmers has examined three boils bacteriologically [2] and isolated an organism which belongs to the group of *Staph. pyogenes aureus*, that subdivision called by Dyar the *Aurococcus mollis*. He has used a vaccine in doses of 500 million on cases with, he asserts, good effect.

After culturing some 30 of these boils I have to submit that the *Staph. aureus* is not the cause of Nile boils, though it may possibly be responsible for the pus formation when that occurs. If this pus be cultured, *Staphylococcus aureus* will almost certainly grow. If, on the other hand, cultural experiments be made at the earlier periods before there is pus formation, then a *Staphylococcus aureus* may sometimes appear, but this, I suggest, is merely an accidental contamination. In every case but one I obtained an organism which at first I took to be a short streptococcus, but which I am now inclined to regard as a white staphylococcus allied to the *S. epidermidis albus* of the skin.

In order to isolate this organism successfully the skin surrounding the boil, the red areola, and the head should be carefully sterilised by swabbing with absolute alcohol. The head should then be lifted off in sterile fashion and a heated test-tube applied to the boil. In a short time the suction as the test-tube cools will induce a slight flow of clear serum. This may then be pipetted off into broth or planted out on a favourable medium such as serum, blood agar, or chocolate medium (I have not ascertained whether primary growth will take place on ordinary agar). Personally I always pipette the serum into Wright's pneumococcus broth, for the reason that after 24 hours the correct organism is easily recognisable by the absence of turbidity and the presence of coarse granules. The culture is also available as a vaccine if required.

Microscopically the organism is an irregular coccus almost always seen in closely apposed pairs lying in clumps and larger than a staphylococcus of the pyogenic type. It does not form chains. On subculture the growth soon becomes turbid. I also noted a curious fact—viz., that though on agar the growth is white, on serum yellow pigment is produced.

The most peculiar property of this white staphylococcus, at any rate from the practical point of view, is its extreme toxicity when used as a vaccine. Believing the organism to be a streptococcus the first dose which I administered was ridiculously small for a staphylococcal vaccine. The case was that of a man who had two small early boils (48 hours), one on each buttock, the first he had ever suffered from. I gave him 10 million. The next day he attended my sick parade, having had four fomentations in the night for the relief of well-nigh intolerable pain, and I found the local reaction had resulted in an inflammation involving nearly the whole of each buttock.

Later on, when I was attempting to immunise men by giving them larger doses, I found that anything over 30 million produced a very considerable swelling and stiffness at the site of inoculation.

III.—*Treatment.*

A. *Preliminary observations.*—I have already mentioned that small doses of vaccine had to be used in septic sores to avoid the production of a fresh crop. I found the same to be true in the case of Nile boils. After a considerable amount of experiment I reached the conclusion that the optimum dose for each vaccine averaged 500,000 germs, and, further, that these small doses should be given about every three days. Further, since both varieties of lesions were prone to occur in the same individual and even where septic sores alone were found, after cure, especially in the hot weather, they were often succeeded by boils, the best treatment seemed to be to give a combined vaccine containing many strains, both from septic sores and also from Nile boils, in doses of 500,000 streptococci and the same number of the boil staphylococcus. Inoculations were given twice weekly and only increased for prophylactic purposes after cure was complete. During the evolution of this routine method, and after it had crystallised, I had under my care something over six hundred cases. The results were very encouraging. The average stay of patients in hospital gives a rough indication of these. It was reduced from about one month to ten days. Further, medical officers who had had experience of sores and boils were well satisfied with the treatment. Notably, Major A. V. Tuke, M.C., R.A.M.C.(T.), surgical divisional officer of the hospital, who permits me to quote a written communication of his on the subject:—

> I have had much experience of septic sores in Gallipoli, Egypt, and Palestine, and I am greatly impressed with the results obtained under vaccine treatment as carried out in this hospital (27th General) under Lieutenant Crowe.

Major Tuke has given me very great assistance in the work, both by his sympathetic attitude and also by many practical suggestions for local treatment, and I am glad to take this opportunity of expressing my appreciation.

B. *Preparation of vaccine.*—The septic sore vaccine. A series of suitable cases showing freely discharging superficial sores should be chosen.

(1) A sore is cleaned up with alcohol.

(2) The serum which presently exudes is taken up in a sterile pipette and dropped into Wright's pneumococcus broth. (Peptone broth plus 6 acid, glucose 1 per cent., fresh human serum 2–5 per cent.)

(3) After 24 hours' incubation the broth is shaken and examined microscopically. It will be found to contain streptococci, practically in pure culture. They will number about 2500 million to the c.cm. Some strains require 48 hours to attain sufficient growth. Counting is unnecessary.

(4) Lysol to make ½ per cent. solution is now mixed with the culture. After thorough shaking the tube should be flamed right down to the surface of the fluid and then left upright in a stand.

(5) Twenty-four hours later the now sterile culture is poured into a stock bottle. For this purpose a sterilised medicine bottle plugged with cotton-wool will serve.

The boil vaccine.

A series of typical young boils in different patients are cleaned up with alcohol, the head lifted, and serum made to exude by means of a heated test-tube, as described before. The subsequent steps of the procedure are as for the septic sore vaccine. In a large majority of the cases 24 hours' incubation of the glucose serum broth will show a granular growth with but slight turbidity except on strenuous shaking.[3]

The growth of this organism may also be taken for all practical purposes as 2500 million per c.cm. (as a rule it is less), and a second stock bottle is gradually filled of boil vaccine.

We have now stock bottles of septic sore vaccine and of boil vaccine, both containing approximately 2500 million to the c.cm. These are now capped with rubber caps, paraffined, thoroughly shaken up, and tested for sterility. From the original stock bottles is made up a lower-strength stock containing 400 million of *each* vaccine to the c.cm. Using a 50 c.cm. vaccine bottle for this purpose, 20,000 million germs (400 by 50) of each kind of vaccine is introduced. This is contained in 8 c.cm. from the original stock bottles. In practice 50 c.cm. vaccine bottles, capped and filled with sterile carbolised saline, are made ready, 16 c.cm. is extracted and replaced by stock vaccine.

For use in treatment the following dilutions are needed: 2 million, 8 million, and 32 million to the 20 minims or c.cm., according to the syringe likely to be used. These figures denote the numbers of germs of *each* vaccine.

Using 50 c.cm. bottles, we arrive near enough to these figures by adding 0·25 c.cm. of the 400-million stock bottle to obtain the lowest dilution—1 c.cm. from the same bottle for the middle dilution and 0·65 c.cm. from each of the original

[2] Journal of Trop. Med. and Hyg., vol. xviii. (1915), p. 205.

[3] Provided the serum taken from the boil is clear—and a boil which discharges pus should not be used—little fear need be entertained that the wrong organism will grow. For purposes of identification, however, it may be taken that the true boil staphylococcus is being cultivated if (1) the germs appear as very closely attached diplococci growing in clumps; (2) the broth shows a granular growth with only slight turbidity; (3) colonies on neutral red egg medium (Dorset's medium, with 1 per cent. glucose and 1 in 10,000 neutral red added) pit the medium, are pink and opaque, and *do not turn orange after 72 hours' growth.*

stock bottles for the strong. The labelling of these bottles should be as distinctive as possible, as a dose given by mistake from the 32-million bottle may result in a very severe relapse

C. *Details of routine treatment.*—Records should be kept of the characters of the lesion, whether superficial or deep sores or membranous (diphtheritic), and in the case of boils whether multiple or single, large or small. Also the length of the history and whether continuous or recurrent.

Vaccine is given in bi-weekly doses of 500,000—i.e., 0·25 c.cm., or 5 minims out of the bottle containing the weakest dilution until all lesions are cured, until no fresh ones appear, and until, in the case of sores, no old superficial scars start weeping afresh after an inoculation.

Vaccines in conjunction with certain surgical measures detailed below will cure the great majority of cases in a remarkably short space of time, but the small doses which are the best for cure have had no effect in preventing relapse. I have found, for instance, that even the omission of one dose is frequently followed by a fresh outbreak. It is therefore essential to continue the vaccine when cure is apparently complete, with increasing doses for prophylactic purposes. After-treatment then should consist in giving doses as follows: 1 million, 2 million, 4 million, still at the same intervals—i.e., bi-weekly, then at intervals of seven days: 8 million, 16 million, and 32 million.

From time to time a case crops up which does not react to the stock vaccine. For these an autogenous vaccine will usually be found to be successful. The routine of doses is the same.

D. *Surgical measures.*—The correct surgical treatment is of the utmost importance, especially in the case of boils. All boils must be incised in such a way as completely to divide the central slough at the earliest possible moment. I desire to lay very particular stress on this point, because in this country it is the custom to wait for a boil to "come to a head" before using the knife. In other words, to wait for pus formation. After the slough of a Nile boil has been completely divided it will not grow any larger, and in the ordinary way will then slowly liquefy and resolve, a process taking from a week to ten days. If, however, the half-million dose of vaccine is given at the same time as the boil is incised cure will be complete after 48 hours. This measure entirely prevents the development of large boils.

Septic sores have a tendency to become covered with a seeping scab. Care should be taken to prevent this by soaking and removal of dried serum. Large actively discharging sores need plain moist dressings, but small healing lesions may be painted with advantage with 1 in 1000 brilliant green in 50 per cent. alcohol and left exposed to the air. It should be remembered that sores over joints always heal with difficulty. These, if possible, should be kept at rest by splinting the limb. Occasionally septic sores become infected with virulent staphylococci, as Colonel Martin has noted, and large ulcers of considerable depth may result. For these it is advisable to give a preliminary dose or two of stock *Staph. aureus* vaccine and keep at absolute rest. 1 in 100 brilliant-green ointment on lint is a good dressing.

Fomentations should only be given for the relief of pain, and are practically never necessary except for deep or membranous septic sores. The only dressing required for incised boils is a piece of cotton-wool strapped across and changed twice a day.

Neglected boils sometimes lead to the formation of chronic sinuses. If these are opened up under an anæsthetic, thoroughly scraped, and then rubbed over with spirit and bipp, they can be stitched up and will heal by first intention.

Membranous sores are diphtheritic and Captain Craig recommends large doses of antitoxin. In addition it will be found that applications of trypsin will remove the membrane. After the ulcer is clear, packing with bipp for three days usually leads to a healthy granulating surface being formed.

Summary.

A vaccine prepared from a large number of strains of streptococci isolated from septic sores, combined with a similar series of a peculiar staphylococcus isolated from Nile boils, when given in frequent small doses, in conjunction with certain surgical measures of which the most important is the early incision of boils, is of great assistance in the cure of these diseases. Increasing the dose of vaccine on the scale described after cure is complete prevents relapse.

In conclusion, I would add that I had intended to make a full study of the organisms, but the exigencies of the times have hitherto prevented my finding the opportunity.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

Outbreak of Typhoid Fever among Inoculated Soldiers.

A MEETING of this section was held on Nov. 8th, Lieutenant-Colonel E. W. GOODALL being in the chair, when a discussion took place on an Outbreak of Typhoid Fever among Inoculated Soldiers.

Captain FRED. M. MEADER, U.S.M.C., gave an account of the epidemiology of the outbreak. He said that on July 11th, 1918, there appeared at an American rest camp the Fourth Casual Company, J A.R.D., Camp ——. Soon after entrance to the camp several cases of fever were brought to the camp hospital. At the time many cases of influenza were present among the soldiers who were passing through this camp, so that no special significance was attributed to the symptoms. After a few days' observation the commanding officer, Captain Logan, suspected that the cases might be typhoid fever. At about the same time a few patients had been sent to a base hospital. Suspicion of typhoid fever was soon aroused, and blood cultures were ordered by Captain Hawn. The district sanitary officer inspected the cases and took specimens of blood from each of the new cases for a culture. *Bacillus typhosus* was isolated from 8 out of 10 cases two days later. During the next month *Bacillus typhosus* was isolated from the blood or fæces of 10 more cases. Altogether 38 soldiers developed typhoid fever at this camp. *Bacillus typhosus* was isolated from 18 of these cases. This organisation left a cantonment on June 15th, 1918, for Camp Merritt, New Jersey. While *en route*, on June 18th, the organisation stopped at Meridan, Mississippi, and was taken for a swim in a lake. The organisation arrived at Camp Merritt on June 21st and embarked on June 28th, and arrived at Liverpool July 10th. After disembarkation the organisation proceeded to ——. At Liverpool 3 cases were left at the Red Cross Hospital, and it is reported that 2 other cases were left at some station *en route*. At the American rest camp 40 soldiers were found ill and transferred to a base hospital, where a diagnosis of typhoid fever was made on 38 of them. From a study of the history of each case it was noted that the date of onset varied over a period of about a month. The first case was ill on leaving Camp Cody. The second developed on June 19th, the third on June 21st, the fourth on June 24th, three on June 26th, four on June 29th, five on July 6th; after which a case developed every day up to the time the organisation arrived at the American rest camp. The organisation left the American rest camp before the diagnosis of typhoid fever had been established, and it had since been learned that 57 other cases developed; this made a total of 95 cases of typhoid fever out of a company of 248 men. In seeking the sources of the infection of this outbreak we naturally turn to the patient who was first ill. With regard to the method of spread it was noted that a considerable group of cases developed during the latter part of the month of June and the early part of July. This suggested a common source of infection; there were two possibilities: 1. That these cases became infected in the train early in the journey. 2. That they became infected bathing in the water at Meridan, Mississippi, on June 18th. The water might easily have been infected by one or two cases of typhoid fever which were present in the organisation at the time. The remaining cases of typhoid fever undoubtedly received their infection by contact with the patients who were ill in the organisation. This could be easily done since the men were crowded together on the train or on shipboard. There were about 1800 men on board the steamer, this number being composed of Casual Companies 4, 10, 11, and 15 and Supply Company 112. Most of these organisations went on to France, and among the members of Casual Company 4, 57 other cases developed, as mentioned above. Infection was limited to No. 4 Casual Company, which suggested that the disease was spread during the swim in the lake at Meridan. All of the above-mentioned cases had been inoculated with either typhoid

vaccine and paratyphoid vaccine or triple typhoid vaccine, or both. Many of them had received several doses in excess of the required number. Also, the men were inoculated at widely different posts and at different times. One patient stated that he received but one dose; otherwise it would seem that the whole organisation was thoroughly immunised. Captain Meader thought that there were three possible explanations of the outbreak: 1. The men might have been unvaccinated or inefficiently vaccinated, but they gave a history of having been vaccinated in different camps at different times, and antibodies were present in their sera. 2. The infection might be due to a new race of organism, but bacteriological tests proved the organism to be that of typhoid; there might, however, be a slight difference in the strain. 3. There might have been an overwhelming dose; this was the most reasonable explanation, as the swimming party included a man with diarrhœa.

Captain CLINTON B. HAWN, U.S.M.C., gave an account of the clinical aspects of the outbreak, which included an account of each of the 40 cases mentioned by Captain Meader. Of these 40 cases, 38 were cases of typhoid In hospital segregation was secured by screening. No case developed as a result of infection whilst in hospital. In dieting the patients they were much handicapped owing to the difficulty in preparing soft food. I. The exact date of *onset* was difficult to decide. Diarrhœa occurred in 58 per cent., constipation in 21 per cent., chill in 10 per cent., and nosebleed in 2·6 per cent. II. Clinical pathology: 1. Low white count was present in all uncomplicated cases. 2. Blood culture was positive in 33 per cent. 3. Stool culture was positive in 25 per cent. 4. The atropine test was positive in 79 per cent. III. Clinical course of disease: 1. The average duration of fever was 35 days: (*a*) Severe high grade typhoid, 70 per cent. 2. Complications: (*a*) Lobar pneumonia occurred in 1 case; (*b*) terminal pneumonia in 1 case; (*c*) broncho-pneumonia in 2 cases; (*d*) hæmorrhage in 3 cases; (*e*) perforation in 1 case; (*f*) phlebitis in 1 case. IV. The mortality was 13 15 per cent.

Captain J. G. HOPKINS, U.S.M.C., said that of the 40 patients in this series admitted to Hursley Hospital as typhoid suspects, the laboratory findings were positive in 25. The results are summarised in the following table:—

	Cases.
B. typhosus isolated from blood and from stool	4
,, ,, ,, ,, blood only	8
,, ,, ,, ,, stool only	5
Typical typhoid lesions at autopsy in cases from which the bacillus was not isolated during life... ... ... (*B. typhosus* isolated post-mortem from 2 of the above.)	3
Typical shift in typhoid agglutinins; blood and stool cultures negative	6

In the remaining 14 cases all laboratory tests were negative, although 13 were clinically cases of typhoid. Of 10 blood cultures taken within a few hours of admission to the hospital 8 were positive irrespective of the stages of the disease. Of 29 cultures taken after patients had been in bed 24 hours only 4 were positive. He thought that this suggested that the physical strain the men had undergone might have caused a persistence of their bacteriæmia. Five fatal cases all showed typical typhoid ulceration of the lower ileum; 1 case showed evidence of recrudescence; extraordinary enlargement of the spleen was found in 2 cases. The complications noted at autopsy were as follows: intestinal hæmorrhage, 1; perforation, 1; thrombosis, 2; pneumonia (pneumococcus type, 1), 1; intramuscular hæmatoma, 1. Titration of agglutinins for typhoid and paratyphoid A and B showed a normal amount of agglutinin for recently vaccinated men. Vaccination records showed that the men were vaccinated at several different camps and at different times, so the possibility that a faulty specimen of vaccine was employed might be excluded. The typhoid bacilli isolated were apparently typical. The laboratory findings offered no explanation of the infection of these men.

Surgeon-General Sir W. B. LEISHMAN said that what struck him most was the remarkable severity of the disease, the number of men attacked, that the infection did not extend to other units, and that though the men were inoculated they still got the fever. The disease as seen in this outbreak was similar to the old typhoid which was known in India, and not the type met with in our army among inoculated men. A case was found occasionally as severe as the old type, but nothing comparable to this had been met with in the B.E.F., nor among the forces in other areas. He had seen a group of men attacked with typhoid of the old type, but on investigation it was found that they were nearly all unvaccinated, the exceptions having been vaccinated two or more years previously. A severe type often occurred in men who had not been lately inoculated. He thought that this was likely to be a case of repeated and massive infection rather than a failure of vaccination in protecting those men. Among them the conditions were such as to cause frequent infection, and a big dose was more likely to override the protection given by inoculation. An abnormal strain was conceivable, but there was no evidence to show the presence of a different strain from the three known strains, and agglutinins had been found in the blood.

Dr. F. FOORD CAIGER suggested that the interval between inoculation and infection was too long for protection to be afforded. He remarked upon the number of cases of severe diarrhœa and said that in severe typhoid diarrhœa was the rule and constipation the exception. Distension of the abdomen should be prevented by proper dieting and the administration of antiseptics.

Lieutenant-Colonel HARVEY said that tests made on the blood of the three men left at Liverpool did not prove the presence of a separate strain. He had not made any tests with regard to virulence.

Sir KENNETH GOADBY said that immunity was only relative and might be overcome in two ways: (1) by successive small doses at short intervals, and (2) by a massive dose. In this case both occurred. The men in the other units would have occasional doses, but those in the same company frequent small doses.

Colonel WILLIAM HUNTER gave an account of an outbreak of typhoid among uninoculated men in Gallipoli, and described the effect of inoculation in decreasing the number of cases. He gave comparative statistics showing the extremely low incidence of the disease in Egypt at the present time. He thought that there must be something wrong with the vaccination of that particular company, as the outbreak was limited to that company only.

Dr. G. S. BUCHANAN also spoke.

Captain MEADER, in reply, said that the men came from different States and were therefore vaccinated by different medical officers and from different batches of vaccines, and therefore he could not think the method of vaccination or the particular vaccine employed could be in fault in every case.

SECTION OF OPHTHALMOLOGY.

Changes in the Cornea which Follow Attacks of Various Forms of Inflammation.

AN ordinary meeting of this section was held on Nov. 6th under the presidency of Mr. W. T. HOLMES SPICER.

The PRESIDENT first thanked the section warmly for having elected him to its post of honour, and then proceeded to give an address, aided by numerous sketches shown by the epidiascope, on "Changes in the Cornea which Follow Attacks of Various Forms of Inflammation." He said this subject had received but small attention in the literature. After ophthalmia neonatorum, sometimes very little was to be seen but the existence of vascular channels, yet the stagnation of the lymph circulation might bring about slowly advancing changes after all the inflammatory appearances had long since subsided. The presence of clear lines in cases of old corneal ulcers had been described by but few observers, although they had been long known and had been seen before the introduction of the loop. Nettleship described the linear paths of clear corneal tissue in large diffuse lipomata, the latter having probably arisen after small spots in infancy; while Fuchs discussed the various linear formations existing in the cornea, suggesting that the lines were due to changes in the lymph system and nebulous area. The best description extant of these lines was that by Sydney Stephenson. In one of his cases the lines traversed a nebula with opacity, and there had been repeated attacks of corneal inflammation early in life. Story stated he had seen lines of this character in interstitial keratitis, and he thought they were due to a clearing of vessels. The picture presented to the observer varied according to the depth of the vessels concerned. Besides the surface invasion of trunk vessels, the terminal capillary loops of the limbus were seen involved, these vessels not arising from any main trunk. This was common in marginal

inflammations, such as trachoma and acute interstitial keratitis, in which vessels invaded the cornea at all depths. It was quite uncommon for vessels to disappear and leave no trace; even though empty of blood they could be seen as silky threads on the surface or as clear lines beneath the surface. The vessels in one layer of the cornea did not interfuse with those in another layer. The first necessity in the production of these conditions was a destruction of tissue. The contraction which followed that either interfered with nutrition or interrupted the flow of lymph, leading to stagnation and the deposit of salts. Arcus senilis was more likely to occur in eyes which have been the subjects of corneal ulceration. The President then dealt in detail with the various forms met with.

On the motion of Mr. E. TREACHER COLLINS, seconded by Mr. W. LANG, the meeting accorded to the President a cordial vote of thanks for his address.

LONDON ASSOCIATION OF MEDICAL WOMEN.—A meeting was held at the House of the Medical Society of London on Nov. 5th, Lady Barrett, the President, being in the chair. The President introduced a discussion on "The Retention of 40 D and Allied Subjects," and read an analysis of the results of the Subcommittee of the Federation of Medical Women which have been considering the subject.—Dr. Louisa Aldrich-Blake, Dr. Marian Thornett-Johnson, Dr. Helen Chambers, Dr. Josephine Fairfield, Dr. Mary Roberts, Dr. Morna Rawlins, and others took part in the discussion, which was adjourned to a date to be fixed later.

Reviews and Notices of Books.

The Statics of the Female Pelvic Viscera. By R. H. PARAMORE, M.D. Lond., F.R.C.S. Eng.; Major, R.A.M.C. (temporary). With 26 illustrations, including 23 plates. London: H. K. Lewis and Co. 1918. Pp. xviii. + 383. 18*s.* net.

IN this book Mr. Paramore further elaborates his well-known views upon the mobility of abdominal organs, and those gynæcologists who still regard the question of uterine position, support, and misplacement as centering around the function and disease of the uterine ligaments, and who look upon the "parametric sling" as an all-important factor in uterine prolapse, will find it desirable to reconsider their position, and to bring, if they can, fresh argument and proof to support their hypothesis. Mr. Paramore stands as the champion of the pelvic floor musculature. He cannot concede these structures as vestigeal tail muscles of the lower vertebrates, of interest only from a morphological standpoint, and functioning feebly by virtue of the fascial coverings. For him they are muscles of high development consequent upon the assumption of the erect posture, and they form an almost complete pelvic diaphragm, in complete nervous sympathy with the general musculature of the abdominal parietes. He pleads with cogency for the conception of the "visceral mass," and maintains that the position of the uterus cannot be considered apart from that of the pelvic viscera in general. He sees the position of these viscera as completely dependent upon the factor of a definite and measurable intra-abdominal pressure acting upon an intact pelvic floor musculature, cunningly arranged to form a sphincter for the pelvic outlet. He shows how the abdominal contents, by virtue of their incompressibility, respond to the ever present downward thrust of the diaphragm above, and bring about the regression of the pelvic floor, and finally establish in equilibrium in the adult pelvis organs which in the fœtus and adolescent are abdominal.

Evidence from phylogeny and ontogeny, from pathological and clinical investigation is in turn called. The arguments seem incontrovertible and it is difficult to believe that Mr. Paramore has not made good his case. The book is one essential to gynæcologists, and which may with advantage be read by others. If Mr. Paramore's contentions are found to be correct they will afford some explanation for the mysteries of visceroptosis, and will help to an understanding of the cause of failure of many of the "organ fixation" types of operation. Many excellent drawings conduce to the apprehension of the arguments and the whole book is presented in a pleasing manner. We congratulate the author upon it and await with interest for the second volume which he promises.
